## Algebraic Structures of Fuchsian Groups: Cyclicity and Centralizers

Hello. In the previous lecture, we explored how, if two elements of  $PSL(2, \mathbb{R})$  or  $PSU(1,1)$  commute with each other, they must share the same fixed points. Building on that foundation, in this lecture, we will delve into some algebraic properties of Fuchsian groups. Specifically, we will demonstrate that if all the elements of a Fuchsian group share a common fixed point, then the group must be cyclic. This result will lead us to an important conclusion: a Fuchsian group cannot contain  $Z \times Z$ . In other words,  $Z \times Z$  is not a Fuchsian group. So, let's begin!

(Refer Slide Time: 01:10)

Theorem: Let  $\Gamma$  be a Fuchsian group such that all non-identity elements of  $\Gamma$  have same fixed point set. Then  $\Gamma$  is cyclic.

Proof:  $T, S \in \Gamma, T \neq S \Rightarrow TS = ST$   $\text{Fix}(T) = \text{Fix}(S)$

- $T \in \Gamma$  s.t.  $T$  is hyperbolic  $\Rightarrow$  all the elements of  $\Gamma$  are hyperbolic
- $\forall \alpha \in \mathbb{R} \quad T(\alpha) = \lambda \alpha \quad T \in \Gamma$
- $\forall S \in \Gamma, \text{Fix}(S) = \{0, \infty\}$
- $S(\alpha) = \mu \alpha$  for some  $\mu \neq 1$
- $\lambda_0 = \inf \{ \mu : S(\alpha) = \mu \alpha \in \Gamma \}$
- $\lambda_0 > 1$   $[\lambda_0 \geq 1, \lambda_0 = 1 \Rightarrow S(\alpha) = \alpha \in \Gamma]$
- Let  $h(\alpha) = \lambda_0 \alpha, h \in \Gamma$
- Claim:  $\Gamma \leq \langle h \rangle$
- Let  $f(\alpha) = \mu \alpha \in \Gamma, \mu > 1$
- Claim:  $\mu = \lambda_0^n$  for some  $n \in \mathbb{N}$
- If  $\mu \neq \lambda_0^n$  for all  $n \in \mathbb{N}$
- $\lambda_0^n < \mu < \lambda_0^{n+1}$
- $\Rightarrow 1 < \frac{\mu}{\lambda_0^n} < \lambda_0$

*Handwritten notes on the right side of the slide:*  
 $\mu > 1 \Rightarrow \lambda_0 = 1$   
 $S(\alpha) = \mu \alpha \in \Gamma$   
 $\mu > 1 \Rightarrow S(\alpha) = \mu \alpha$   
 $\Rightarrow S^n(\alpha) \rightarrow id$   
 $\Rightarrow S^n \in \Gamma$   
 $\Rightarrow S^n = id$   
 This is a contradiction

The first theorem is as follows: Let us consider a Fuchsian group, and suppose that all the non-identity elements of this Fuchsian group share the same fixed point set. We will prove that, under this condition, the Fuchsian group must be cyclic.

Let's begin by considering a Fuchsian group  $\Gamma$ , with the assumption that for any two elements  $T$

and  $S$ , both non-identity, their fixed point sets are the same. From a previous lemma or theorem, we know that this implies that  $T$  and  $S$  commute, i.e.,  $T \circ S = S \circ T$ . Since  $T$  belongs to  $\Gamma$ , we assume that  $T$  is hyperbolic. This would imply that all elements of  $\Gamma$  are hyperbolic because, if we take another element  $S'$ , the fixed point set of  $S'$  would also be the same as that of  $T$ , which is a two-point set, characteristic of hyperbolic transformations. Hence, every element of  $\Gamma$  is hyperbolic.

Now, without loss of generality, we can assume that the transformation  $T(z)$  takes the form  $T(z) = \lambda z$ , where  $T$  belongs to  $\Gamma$ . Since the fixed point set of  $T$  is  $\{0, \infty\}$ , it follows that for all  $S \in \Gamma$ , the fixed point set of  $S$  must also be  $\{0, \infty\}$ , and hence  $S(z)$  must take the form  $S(z) = \mu z$ , for some real positive  $\mu \neq 1$ .

Our goal now is to prove that  $\Gamma$  is a cyclic group. To do this, we need to find a generator for this cyclic group. We start by considering the element  $T$ , which is hyperbolic. Let  $\lambda_0$  be defined as the infimum of all such  $\mu$  values, where the isometry  $S(z) = \mu z$  belongs to  $\Gamma$  and  $\mu > 1$ . Thus,  $\lambda_0$  is defined as the smallest such  $\mu$ .

The next claim is that  $\lambda_0 > 1$ . Now, let  $S(z) = \lambda_0 z$ . We will prove that  $\Gamma$  is generated by  $h$ , where  $h(z) = \lambda_0 z$ .

Thus, there are two key claims here: first, that  $\lambda_0 > 1$ , and second, that if  $h(z) = \lambda_0 z$ , then  $\Gamma$  is generated by  $h$ , making  $\Gamma$  a cyclic group. Now, let's address the first claim, that  $\lambda_0 > 1$ . First, observe that  $\lambda_0$ , being the infimum of all  $\mu$ , where  $\mu > 1$ , must satisfy  $\lambda_0 \geq 1$ . What we need to do next is rule out the possibility that  $\lambda_0 = 1$ .

Let's assume, for contradiction, that  $\lambda_0 = 1$ . Suppose there exists a sequence  $\mu_n$  converging to  $\lambda_0$ , with each  $\mu_n$  greater than 1, and consider the transformations  $S_n(z) = \mu_n z$ , where each  $S_n$  belongs to  $\Gamma$ . Since  $\mu_n \rightarrow 1$ , the transformation  $S_n(z)$  converges to the identity map, i.e.,  $S_n(z) \rightarrow z$ .

However, this creates a problem.  $\Gamma$  is a Fuchsian group, and by definition, it is a discrete group. But if  $S_n$  converges to the identity, we get a contradiction, as discreteness implies there cannot be a sequence of distinct elements converging to the identity. This contradiction shows that  $\lambda_0 > 1$ .

Now, moving to the second claim:  $\Gamma$  is generated by  $h(z) = \lambda_0 z$ . To prove this, let's consider an

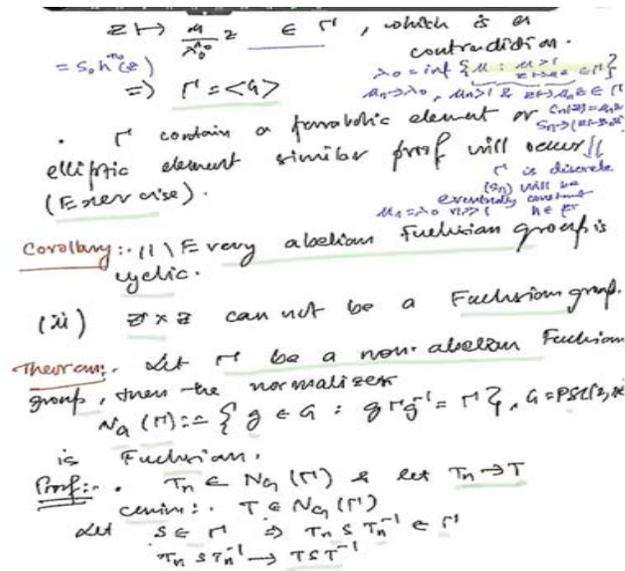

arbitrary element  $f(z) = \mu z$  that belongs to  $\Gamma$ , where  $\mu > 1$ . The claim is that  $\mu = \lambda_0^n$  for some natural number  $n$ .

If this were not true, i.e., if  $\mu$  could not be written as  $\lambda_0^n$  for any natural number  $n$ , then there would exist some  $n_0$  such that  $\mu$  lies strictly within the open interval  $(\lambda_0^{n_0}, \lambda_0^{n_0+1})$ . This implies that:

$$1 < \frac{\mu}{\lambda_0^{n_0}} < \lambda_0$$

This inequality contradicts the fact that  $\lambda_0$  is the smallest such value in  $\Gamma$ , proving that  $\mu = \lambda_0^n$  for some natural number  $n$ . Hence,  $\Gamma$  is generated by the transformation  $h(z) = \lambda_0 z$ , confirming that  $\Gamma$  is indeed a cyclic group.

(Refer Slide Time: 09:32)

Now, let's revisit the argument and clarify it step by step. The expression  $\frac{\mu}{\lambda_0^{n_0}} < \lambda_0$  essentially defines a mapping that we are working with here. So, consider the map  $f(z) = \mu z$ , which we know belongs to  $\Gamma$ . Additionally, the map  $h(z) = \lambda_0 z$  also belongs to  $\Gamma$ , and we will explain why this is the case.

We have assumed that  $f(z) = \mu z$  is in  $\Gamma$ , and it's important to note that  $h(z) = \lambda_0 z$  also belongs to  $\Gamma$ . But why does  $h$  belong to  $\Gamma$ ? We need to prove this. So, let's establish this reasoning clearly.

Recall that  $\lambda_0$  is the infimum of all  $\mu$ , where  $\mu > 1$  and the mapping  $z \mapsto \mu z$  belongs to  $\Gamma$ . From this, we can construct a sequence  $\mu_n$  that converges to  $\lambda_0$ , with each  $\mu_n > 1$  and each mapping  $S_n(z) = \mu_n z$  also belonging to  $\Gamma$ . Since  $\mu_n \rightarrow \lambda_0$ , the transformations  $S_n(z)$  converge to the map  $z \mapsto \lambda_0 z$ .

At this point, since  $\Gamma$  is discrete, the sequence  $S_n$  must eventually become constant. In other words, for sufficiently large  $n$ , the sequence  $\mu_n$  will stabilize, meaning that for large enough  $n$ ,  $\mu_n = \lambda_0$ . This shows that the map  $h(z) = \lambda_0 z$  indeed belongs to  $\Gamma$ .

Thus, we have proven that  $h$  belongs to  $\Gamma$ . Consequently, any power of  $h$ , whether positive or negative, also belongs to  $\Gamma$ . Now, consider the composition  $S \circ h^{-n_0}(z)$ , which is equal to  $\frac{\mu}{\lambda_0^{n_0}} z$ .

This map belongs to  $\Gamma$ , as it is composed of elements from  $\Gamma$ .

However, here lies the contradiction: we assumed  $\frac{\mu}{\lambda_0^{n_0}} < \lambda_0$ , which implies that there is a value less than the infimum  $\lambda_0$  such that the map  $z \mapsto \frac{\mu}{\lambda_0^{n_0}} z$  belongs to  $\Gamma$ . But this contradicts the fact that  $\lambda_0$  is the smallest such value in  $\Gamma$ .

Therefore, the contradiction arises due to our assumption, meaning that  $\mu$  must be equal to  $\lambda_0^n$  for some natural number  $n$ .

Thus, we conclude that  $f = h^n$  for some natural number  $n$ . Consequently, we have shown that  $\Gamma$  is a cyclic group generated by the element  $h$ .

Now, if  $\Gamma$  contains either a parabolic or elliptic element, the proof follows in a similar manner, so I will leave that as an exercise for you. As a direct corollary of this result, one can deduce that every Abelian Fuchsian group must also be cyclic. This is because, in any Abelian Fuchsian group, the elements commute with one another, which implies that they must all share the same fixed point set. By the theorem we just proved, this forces the group to be cyclic.

For example, the group  $Z \times Z$  is an Abelian group but not cyclic, so it can never be a Fuchsian group. This gives us an important takeaway:  $Z \times Z$  is not a Fuchsian group.

Now, let's move to the next theorem. It states that if we take a non-Abelian Fuchsian group, the normalizer of that group within  $\text{PSL}(2, R)$  is also Fuchsian. But first, what do we mean by the

normalizer? In the group  $G = \text{PSL}(2, R)$ , the normalizer of  $\Gamma$  is the set of all elements  $g \in G$  such that  $g \Gamma g^{-1} = \Gamma$ , meaning  $\Gamma$  is a normal subgroup within this normalizer.

To prove this, we begin by taking a sequence of elements  $T_n$  from the normalizer, and we assume that this sequence converges to some element  $T$ . Our first claim is that this limit  $T$  also belongs to the normalizer.

Let's take any element  $S \in \Gamma$ , and consider that each  $T_n$  belongs to the normalizer of  $\Gamma$ . This means that  $T_n S T_n^{-1} \in \Gamma$ , for all  $T_n$ . Now, since  $T_n \rightarrow T$ , we can conclude that  $T_n S T_n^{-1} \rightarrow T S T^{-1}$ , and it's straightforward to verify that this implies  $T S T^{-1} \in \Gamma$ , proving that  $T$  is indeed in the normalizer.

**(Refer Slide Time: 19:00)**

$$\begin{aligned}
 & T_n S T_n^{-1} \in \Gamma \\
 & \Gamma \text{ Fuchsian group} \\
 & \Gamma \ni T_n S T_n^{-1} = T S T^{-1} \text{ for all large } n \\
 & \Rightarrow T \in N_G(\Gamma) \\
 & \cdot T_n \in N_G(\Gamma) \text{ \& } T_n \rightarrow T \\
 & \quad T \in N_G(\Gamma) \\
 & \text{Claim: } T_n = T \text{ for large } n \\
 & \text{Suppose not, } T^{-1} T_n \rightarrow \text{id} \\
 & \text{let } P_n = T^{-1} T_n \in N_G(\Gamma) \\
 & \quad P_n \rightarrow \text{id} \text{ \& } P_n \neq \text{id} \forall n \\
 & \text{let } S \in \Gamma \\
 & \quad P_n S P_n^{-1} \rightarrow S \\
 & \quad \in \Gamma \\
 & \Gamma \text{ Fuchsian} \\
 & P_n S P_n^{-1} = S \text{ for all } n \geq n_0 \\
 & \Rightarrow \text{Fix}(S) = \text{Fix}(P_n) \\
 & \text{or } S' \in \Gamma \\
 & \text{Fix}(S') = \text{Fix}(P_n) \Rightarrow n \geq n_0 \\
 & \text{Fix}(S') = \text{Fix}(e) \Rightarrow S S' = S' S \text{ \& } S S' = S' S \\
 & \Rightarrow \Gamma \text{ is abelian}
 \end{aligned}$$

So, we have  $T_n S T_n^{-1} \in \Gamma$ , and since we started with  $\Gamma$  as a Fuchsian group, this implies that the sequence  $T_n S T_n^{-1}$  will eventually become constant. Consequently, we have the following:  $T_n S T_n^{-1} = T S T^{-1}$  for sufficiently large  $n$ . Given that  $T_n S T_n^{-1} \in \Gamma$ , it follows that  $T S T^{-1}$  must also belong to  $\Gamma$ .

Now, since  $S \in \Gamma$ , was arbitrary, we have shown that  $T S T^{-1} \in \Gamma$ , which implies that  $T$  is in the normalizer of  $\Gamma$ . Therefore, we have successfully proved that if a sequence  $T_n$  from the normalizer converges to  $T$ , then  $T$  also belongs to the normalizer.

To establish that the normalizer of  $\Gamma$  is a Fuchsian group, we must further demonstrate that the sequence  $T_n$  is eventually constant, i.e.,  $T_n = T$  for all sufficiently large  $n$ . Suppose, for contradiction, that this is not the case, and that  $T_n$  is a distinct sequence. While  $T_n$  converges to  $T$ , the difference  $P_n = T^{-1}T_n$  must converge to the identity. Since both  $T$  and  $T_n$  belong to the normalizer, it follows that  $P_n = T^{-1}T_n \in$  the normalizer as well, and  $P_n \rightarrow \text{Identity}$  by our assumption.

However, we have also assumed that  $T_n$  is not eventually constant, meaning  $P_n \neq \text{Identity}$  for all  $n$ . Now, take any element  $S \in \Gamma$ . Since  $P_n \in$  the normalizer, it follows that  $P_n S P_n^{-1} \in \Gamma$ . Moreover, since  $P_n \rightarrow \text{Identity}$ , we have  $P_n S P_n^{-1} \rightarrow S$ . But because  $\Gamma$  is a Fuchsian group, which is discrete, this convergence implies that  $P_n S P_n^{-1} = S$  for large  $n$ , resulting in a contradiction.

Therefore, our assumption that  $P_n \neq \text{Identity}$  was incorrect, and we conclude that the sequence  $T_n$  must be eventually constant, i.e.,  $T_n = T$  for all large  $n$ . This completes the proof that the normalizer of a non-Abelian Fuchsian group is itself a Fuchsian group.

Therefore, this sequence  $P_n$  will eventually become constant. Consequently, for all sufficiently large  $n$ , we have  $P_n S P_n^{-1} = S$ , which demonstrates that the fixed points of  $S$  are the same as those of  $P_n$  for all  $n \geq n_S$ . Now, let us consider another element  $S' \in \Gamma$ . Similarly, for all  $n \geq n_{S'}$ , the fixed points of  $S'$  will also coincide with those of  $P_n$ .

Now, let us take  $n \geq \max(n_S, n_{S'})$ . In this case, the fixed points of  $S$  are equal to the fixed points of  $P_n$ , and the fixed points of  $P_n$  are equal to the fixed points of  $S'$ . Thus, the fixed points of  $S$  and  $S'$  are the same. By a theorem we established in the previous class, this implies that  $S$  and  $S'$  commute with each other.

Since  $S$  and  $S'$  were arbitrary elements of  $\Gamma$ , we have proven that all elements of  $\Gamma$  commute with one another. This proves that  $\Gamma$  is abelian. However, we began by assuming that  $\Gamma$  is nonabelian, leading to a contradiction. The contradiction arises from the assumption that  $T_n$  is not an eventually constant sequence.

Therefore, the sequence  $T_n$  must be eventually constant, meaning  $T_n = T$  for all sufficiently large  $n$ . This ultimately implies that the normalizer of  $\Gamma$  is indeed a Fuchsian group.
