Hyperbolic Groups and the Properties of Quasi-Convex Subgroups

(Refer Slide Time: 00:13)

Theorem: Intersection of two quasi-convex subgroups in a hyperbolic group is again quasi-convex.

Proof: Let H_1, H_2 be two k -quasi-convex subgroups of a hyperbolic group G .

Let $h \in H_1 \cap H_2$ & $[1, h]$ be a geodesic in G joining 1 and h .

For each vertex v in $[1, h]$ $\exists x \in H_1, y \in H_2$ such that $d(v, x) \leq k$ and $d(v, y) \leq k$

$\Rightarrow d(1, v'x) \leq k$ & $d(1, v'y) \leq k$.

Let $V_0 =$ number of elements in the

Hello! In this lecture, we will demonstrate that the intersection of two quasi-convex subgroups within a hyperbolic group is itself a quasi-convex subgroup. Additionally, we will use this result to show that a hyperbolic group cannot contain an abelian subgroup of rank greater than or equal to 2.

Let's begin by proving this theorem. Consider H_1 and H_2 as two k -quasi-convex subgroups within a hyperbolic group G . Now, let's take an element h that lies in the intersection of these two groups, H_1 and H_2 . We will join 1 and h by a geodesic in the group G .

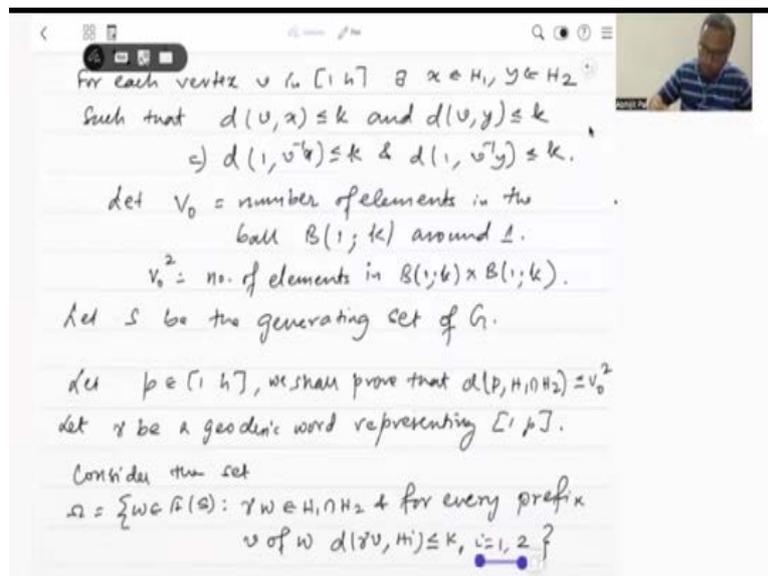

Our goal is to show that for any vertex v on this geodesic from 1 to h , there exists a vertex v' in the intersection $H_1 \cap H_2$ such that the distance between v and v' is less than or equal to a function of k and the hyperbolicity constant of the group G .

For each vertex v on the geodesic connecting 1 to h , we can find vertices $x \in H_1$ and

$y \in H_2$ such that the distance from v to x is less than or equal to k , and the distance from v to y is also less than or equal to k . This property holds because both H_1 and H_2 are k -quasi-convex.

Consequently, this implies that the distance from 1 to $v^{-1}x$ is less than or equal to k , and the distance from 1 to $v^{-1}y$ is likewise less than or equal to k .

(Refer Slide Time: 02:21)

Now, let us define v_0 as the number of elements in the ball of radius k centered around 1 . Consequently, v_0^2 will represent the number of elements in the Cartesian product of these two balls $B_1(k)$. We also take S to be the generating set of the group G .

Our aim is to prove that for any vertex p on the geodesic connecting 1 to h , the distance from p to the intersection $H_1 \cap H_2$ is less than or equal to v_0^2 . This will demonstrate that $H_1 \cap H_2$ is a quasi-convex subgroup.

Let γ be a geodesic word representing the path from 1 to p . We will now consider the following set. We define the set Ω as the collection of all words w that belong to the free group generated by S such that the concatenation of γ and w is an element of the intersection $H_1 \cap H_2$. Furthermore, for every prefix v of w , the distance between γv and H_i is less than or equal to k , where i is either 1 or 2 .

Let me illustrate this concept with a diagram. We have the set Ω in focus. First, we take an element h that belongs to the intersection $H_1 \cap H_2$. We connect 1 to h via a geodesic.

Next, consider an element p that lies on this geodesic. The geodesic path from 1 to p is represented by the word γ .

(Refer Slide Time: 04:08)

The image shows handwritten notes on a whiteboard. On the left, it says: "for each $v \in V$ ", "Such that", "let V_0 ", " $V_0^2 =$ ", "let S be", " $\forall u, p \in [1, p]$ ", "let γ be a", "Consider the", " $\Omega = \{w \in F(S) \mid$ ". In the center, there is a diagram of a tree-like structure with a root node 1 and a path γ leading to a node p . A shaded region $H_1 \cap H_2$ is shown around the path. Distances are labeled: $d(\gamma u, H_1) \leq k$ and $d(\gamma u, H_2) \leq k$. On the right, it says: " $H_1, \gamma \in H_2$ ", " $d(\gamma, y) \leq k$ ", " $d(\gamma, y) \leq k$ ", "in the", "and \perp ", " $\times B(1, k)$ ", " G ", " $\chi(p, H_1 \cap H_2) = V_0^2$ ", " $\gamma [1, p]$ ", "any prefix".

Now, what exactly is the set Ω ? It consists of all those words w in the free group generated by S such that when you concatenate γ with w , denoted as γw , you reach a vertex γw that lies within $H_1 \cap H_2$. If I take any vertex along this path, labeled by a subword u , that vertex corresponds to γu . The distances from γu to H_1 and H_2 are both less than or equal to k .

(Refer Slide Time: 07:37)

The image shows handwritten notes on a whiteboard. It says: " $\Omega \neq \emptyset$ and $w_0 \in \Omega$ be a word of minimal length.", "Claim: $|w_0| \leq V_0^2$.", "If possible, let $|w_0| > V_0^2$ ". Below this is a diagram showing a path γ from a root node 1 to a node w_0 . A shaded region $H_1 \cap H_2$ is shown around the path. Distances are labeled: $d(\gamma u, H_1) \leq k$ and $d(\gamma u, H_2) \leq k$. Below the diagram, it says: " $\gamma w_0 \in H_1 \cap H_2$ ".

Having defined the set Ω , we can assert that it is non-empty. This is because, if we consider the geodesic path connecting v to h , let's denote this geodesic word as w_1 . The word w_1 will belong to Ω since γw_1 is equal to h , which indeed lies in the intersection $H_1 \cap H_2$. Moreover, since both H_1 and H_2 are quasi-convex, any vertex on this path will have a distance to H_1 or H_2 that is less than or equal to k . Therefore, we conclude that the set Ω is indeed non-empty.

Thus, we can conclude that the set Ω is non-empty. Now, let's denote w_0 as an element of Ω that has minimal length. It is indeed possible to identify such a word within Ω that exhibits this minimal length property. The claim we wish to establish is that the length of w_0 is less than or equal to v_0^2 . If we can demonstrate this, then our proof will be complete.

However, let's assume for the sake of contradiction that the length of w_0 is strictly greater than v_0^2 . This assumption will lead us to explore the implications further.

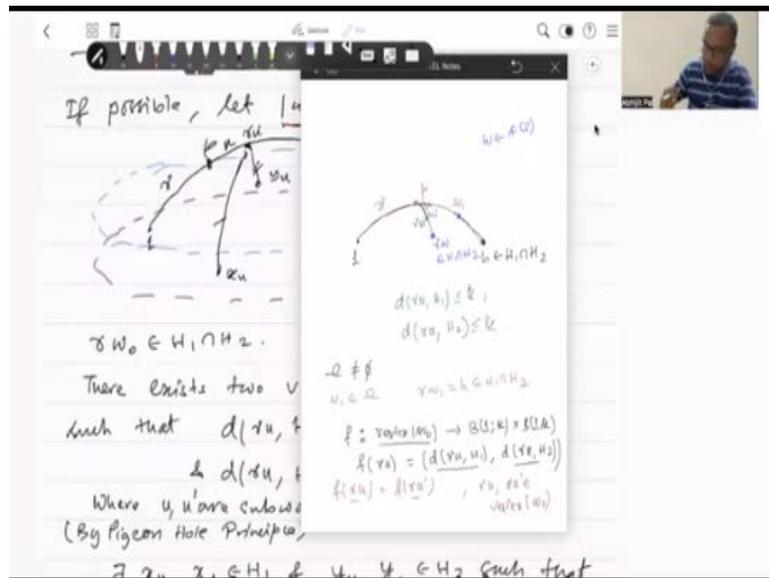

(Refer Slide Time: 08:41)

$\gamma w_0 \in H_1 \cap H_2$.
 There exists two vertices $\gamma u, \gamma u' \in w_0$
 such that $d(\gamma u, H_1) = d(\gamma u', H_1)$
 & $d(\gamma u, H_2) = d(\gamma u', H_2)$.
 Where u, u' are subwords of w_0 & $|u| < |u'|$
 (By Pigeon Hole Principle)
 $\exists x_u, x_{u'} \in H_1$ & $y_u, y_{u'} \in H_2$ such that
 $(\gamma u)^{-1} x_u = (\gamma u')^{-1} x_{u'}$ & $(\gamma u)^{-1} y_u = (\gamma u')^{-1} y_{u'}$

Given our setup, we have that γw_0 belongs to the intersection $H_1 \cap H_2$, as defined by our set Ω . Now, by applying the Pigeonhole Principle, we can conclude that there exist two vertices, γu and $\gamma u'$, within the word w_0 such that the distance from γu to H_1 is equal to the distance from $\gamma u'$ to H_1 . Similarly, the distance from γu to H_2 is equal to the distance from $\gamma u'$ to H_2 .

But why does this hold true? The reasoning stems from the fact that w_0 is constructed from a finite number of vertices along the geodesic. When we explore the distances to the quasi-convex subgroups H_1 and H_2 , the properties of quasi-convexity dictate that there cannot be too many distinct distance values. Hence, by the Pigeonhole Principle, some vertices must share the same distances to both H_1 and H_2 .

(Refer Slide Time: 09:36)

Let us consider a function f defined from the vertex set of w_0 to the Cartesian product of two balls. Specifically, for a vertex γu , we define $f(\gamma u)$ as the ordered pair consisting of the distance from γu to H_1 and the distance from γu to H_2 .

The first coordinate of this ordered pair will belong to the ball of radius k around the identity because the distance from γu to H_1 is less than or equal to k . Similarly, the second coordinate will also be within this ball, as the distance from γu to H_2 is likewise bounded by k .

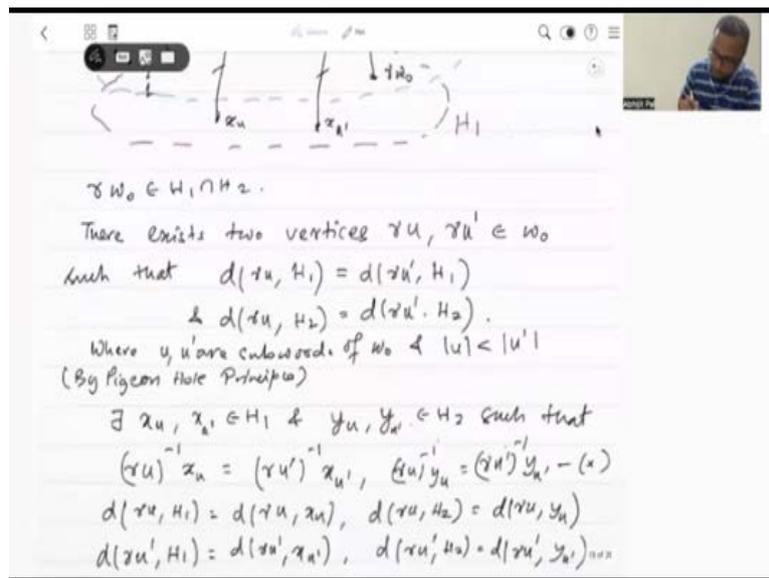

Now, let's analyze the cardinality of the domain of this function f . The domain's cardinality is equal to the length of w_0 . Given our earlier assumption, we took the length of w_0 to be greater than v_0^2 .

Thus, according to the Pigeonhole Principle, since the cardinality of the domain (the length of w_0) exceeds that of the codomain (which is limited by the product of two balls of radius k), there must exist two elements, say γu and $\gamma u'$, in the vertex set of w_0 such

that $f(\gamma u) = f(\gamma u')$.

Consequently, we find that there exist two vertices, γu and $\gamma u'$, both belonging to w_0 , such that the distance from γu to H_1 is the same as the distance from $\gamma u'$ to H_1 , and the distance from γu to H_2 is equal to the distance from $\gamma u'$ to H_2 . Moreover, we can select these subwords u and u' from w_0 such that the length of u is strictly less than the length of u' .

(Refer Slide Time: 13:44)

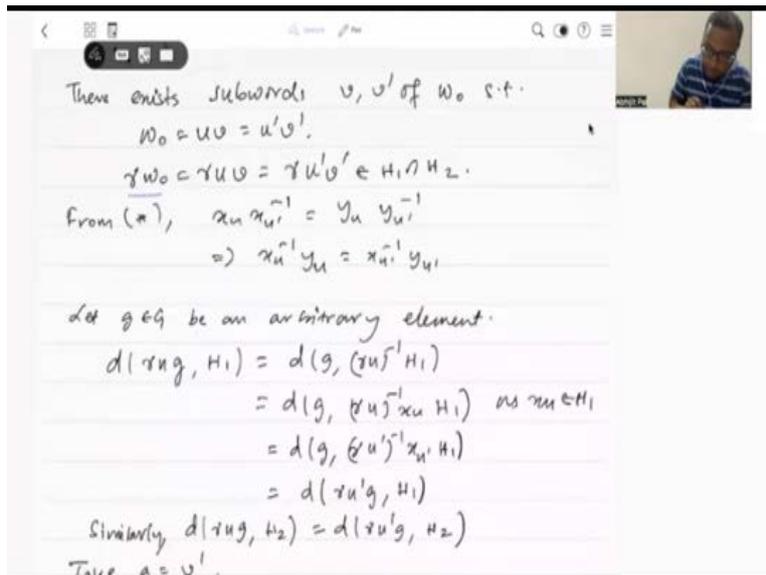

Therefore, we can conclude that there exist points x_u and $x_{u'}$ that belong to H_1 , as well as points y_u and $y_{u'}$ that belong to H_2 , such that the distance from γu to x_u is the same as the distance from $\gamma u'$ to $x_{u'}$. This means that these two geodesics are labeled by the same word, which we can express as $\gamma u^{-1} x_u = \gamma u'^{-1} x_{u'}$.

Similarly, the distance from γu to y_u is identical to the distance from $\gamma u'$ to $y_{u'}$. Here, both x_u and $x_{u'}$ lie within H_1 , while y_u and $y_{u'}$ are elements of H_2 . We can also state that $\gamma u^{-1} y_u = \gamma u'^{-1} y_{u'}$.

Now, let's visualize this situation. The word w_0 , which belongs to our set ω , represents the minimal length path. We have established two vertices, γu and $\gamma u'$, along this path, such that the distance from γu to x_u equals the distance from $\gamma u'$ to $x_{u'}$. Similarly, the distance from γu to y_u matches the distance from $\gamma u'$ to $y_{u'}$. Notably, x_u and $x_{u'}$ are both in H_1 , while y_u and $y_{u'}$ belong to H_2 .

(Refer Slide Time: 16:07)

Now, we can identify subwords v and v' of w_0 such that w_0 can be expressed as $u v$ and also as $u' v'$. If we refer back to our previous diagram, we can see that this path is labeled by w_0 . Specifically, w_0 is represented as the concatenation of u followed by the geodesic labeled by v . Similarly, it can also be expressed as u' followed by the segment labeled v' .

Therefore, we have γw_0 equal to $\gamma u v$ and also equal to $\gamma u' v'$, which means that this expression lies within the intersection $H_1 \cap H_2$.

Now, let's analyze the implications of this equation. From the relationships established, we find that $x_u x_u'^{-1} = y_u y_u'^{-1}$. This implies that $x_u^{-1} y_u = x_u'^{-1} y_u'$.

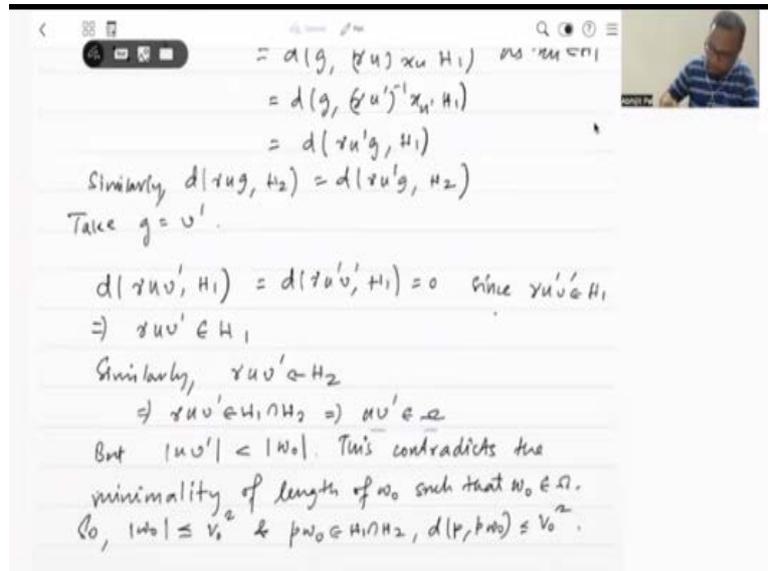

What this tells us is that if we consider the geodesic connecting x_u and y_u , its labeling will be identical to that of the geodesic connecting $x_{u'}$ and $y_{u'}$. This suggests a strong structural similarity between the paths defined by these vertices, reinforcing the coherence of our findings in this context.

Now, let's take note of our observations and proceed by considering g as an arbitrary element of the group G . We need to examine the distance between $\gamma u g$ and H_1 . This distance is equal to the distance between $g \gamma u^{-1}$ and H_1 , because x_u belongs to H_1 .

From this relationship, we can express the distance between $g \gamma u^{-1} x_{u'}$ in a similar fashion. This distance is equivalent to the distance between $g \gamma u'^{-1} x_{u'}$ and H_1 due to the

equality we established earlier. Thus, we can also say that this distance is the same as that between $\gamma u' g$ and H_1 .

(Refer Slide Time: 18:23)

Furthermore, the distance between $\gamma u g$ and H_2 will also match the distance between $\gamma u' g$ and H_2 . Now, let's specifically set g to be v' . While we've considered g as an arbitrary element, we can indeed take g to be v' . Consequently, the distance between $\gamma u v'$ and H_1 is equal to the distance between $\gamma u' v'$ and H_1 . Since both of these elements lie in H_1 , this distance will be zero.

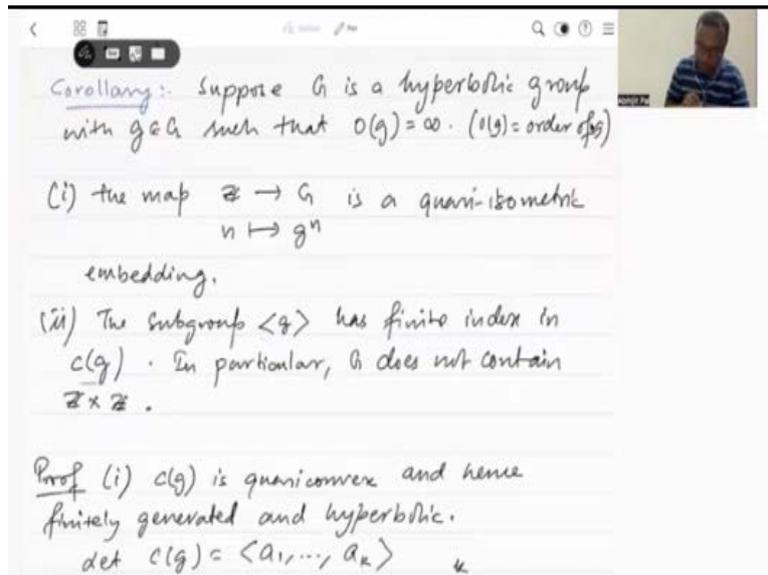

So, when we substitute g with v' in our equation, we find that the distance equals zero, which implies that $\gamma u v'$ must belong to H_1 . Similarly, we can conclude that $\gamma u v'$ also belongs to H_2 . Therefore, it follows that $\gamma u v'$ is an element of both H_1 and H_2 , meaning that $\gamma u v'$ belongs to the intersection $H_1 \cap H_2$.

This establishes that $u v'$ is indeed an element of the set Ω .

Now, if we look back at our earlier illustration, we can see that u followed by v' belongs to Ω . The length of $u v'$ is strictly less than the length of w_0 , which directly contradicts our assumption regarding the minimality of the length of w_0 .

Thus, we conclude that the length of w_0 must be less than or equal to v_0^2 . Additionally, since $p w_0$ lies within $H_1 \cap H_2$ and the distance between p and $p w_0$ is at most v_0^2 , we have effectively proven that the intersection $H_1 \cap H_2$ is a quasi-convex subgroup.

(Refer Slide Time: 22:17)

Now, as a corollary, we can draw some significant conclusions. Let's consider G to be a hyperbolic group with an element g such that the order of g is infinite. Our first observation is that if we define a map from \mathbb{Z} to G given by $n \mapsto g^n$, this map serves as a quasi-isometric embedding.

The second point requires proof. Specifically, the subgroup generated by g forms an infinite cyclic subgroup, which has a finite index within its centralizer. This leads to a crucial implication: a hyperbolic group cannot contain $\mathbb{Z} \times \mathbb{Z}$.

To understand why, suppose for the sake of argument that G does contain $\mathbb{Z} \times \mathbb{Z}$. If we take the generator of the \mathbb{Z} component, it will represent an element of infinite order. Consequently, this would imply that the centralizer must contain $\mathbb{Z} \times \mathbb{Z}$ as well.

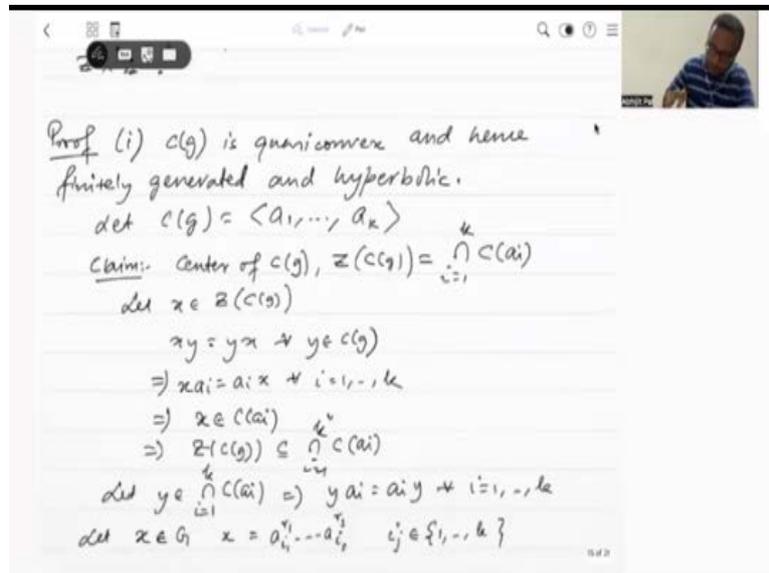

However, if the centralizer indeed contains $\mathbb{Z} \times \mathbb{Z}$, then the index of the cyclic subgroup generated by g would not be finite within the centralizer. This situation leads to a contradiction, indicating that our initial assumption, that the hyperbolic group G contains $\mathbb{Z} \times \mathbb{Z}$, must be false.

Therefore, we conclude that the hyperbolic group G cannot contain $\mathbb{Z} \times \mathbb{Z}$. Now, let us first focus on proving the assertion that the map from \mathbb{Z} to G , defined by $n \mapsto g^n$, is indeed a quasi-isometric embedding.

We have already established that the centralizer of an element is quasi-convex, which

implies that it is finitely generated and, consequently, hyperbolic. Let's denote the centralizer of g as C_G , generated by a_1, a_2, \dots, a_k . Our first claim is that the center of this centralizer is the intersection of the centralizers of each a_i , where a_i forms the generating set of C_G .

(Refer Slide Time: 24:18)

So, how do we prove this claim?

First, let's take an element x that resides in the center of the centralizer of g . This means that x commutes with every element in the centralizer. In particular, for each a_i , we have $xa_i = a_ix$. Therefore, we can conclude that x belongs to C_{a_i} for all i ranging from 1 to k . This shows that the center of the centralizer of g is indeed contained within this intersection of the centralizers.

Now, let's examine the converse. Suppose we take any element y that belongs to this intersection. This means that $ya_i = a_iy$ for all i from 1 to k .

Next, consider any element x in g . We can express x as a product of the generators a_i . This establishes a connection between elements in the centralizer and their behavior in relation to x .

Now, if we consider the element xy and express it in relation to the generators a_i , we find that y commutes with each of these generators. Consequently, we can equate this element to another expression, ultimately concluding that it is equal to yx . This leads

us to the conclusion that x indeed belongs to the center of the centralizer.

(Refer Slide Time: 25:50)

$xy = a_1^{r_1} \dots a_n^{r_n} y = y a_1^{r_1} \dots a_n^{r_n} = yx$
 $\Rightarrow x \in Z(C(G))$

Every $C(a_i)$ is quasi-convex in G
 $\Rightarrow Z(C(G)) = \bigcap_{i=1}^n C(a_i)$ is a quasi-convex
 subgroup of G & hence a hyperbolic group.
 (Exercise: An abelian group is hyperbolic if and
 only if it is virtually cyclic)
 Thus $Z(C(G))$ is virtually cyclic i.e. \exists a cyclic
 subgroup of finite index in $Z(C(G))$
 This implies $[Z(C(G)) : \langle q \rangle] < \infty$

$\Rightarrow \langle q \rangle$ is quasi-convex in $Z(C(G))$

$\hookrightarrow \langle q \rangle \xrightarrow{q.i} Z(C(G)) \xrightarrow{q.i} C(G) \xrightarrow{q.i} G$
 ($q.i$: quasi-isometric embedding)

Next, it is important to note that each centralizer of the generators a_i forms a quasi-convex subgroup within the hyperbolic group. The center of the centralizer, being the finite intersection of these quasi-convex subgroups, will itself be a quasi-convex subgroup of G . Therefore, we can assert that the center of the centralizer is also a hyperbolic group.

(Refer Slide Time: 26:45)

$\Rightarrow Z(C(G)) = \bigcap_{i=1}^n C(a_i)$ is a quasi-convex
 subgroup of G & hence a hyperbolic group.
 (Exercise: An abelian group is hyperbolic if and
 only if it is virtually cyclic)
 Thus $Z(C(G))$ is virtually cyclic i.e. \exists a cyclic
 subgroup of finite index in $Z(C(G))$
 This implies $[Z(C(G)) : \langle q \rangle] < \infty$
 $\Rightarrow \langle q \rangle$ is quasi-convex in $Z(C(G))$

$\hookrightarrow \langle q \rangle \xrightarrow{q.i} Z(C(G)) \xrightarrow{q.i} C(G) \xrightarrow{q.i} G$
 ($q.i$: quasi-isometric embedding)

This exercise demonstrates that if we take any abelian group that is hyperbolic, it will

necessarily be virtually cyclic. The term "virtually cyclic" refers to the existence of a cyclic subgroup with finite index. This is a crucial concept, and it's worth noting that the converse is also true.

Given that our group is abelian and we have established that it is a hyperbolic group, we can apply the findings from this exercise to conclude that this group must indeed be virtually cyclic. This indicates that there exists a cyclic subgroup of finite index within the center of the centralizer. As a result, we can infer that the index of this infinite cyclic subgroup within the center of the centralizer is finite. Consequently, this implies that the cyclic subgroup is quasi-convex in the center of the centralizer.

Therefore, we have a quasi-convex subgroup of the center of the centralizer. By referencing a previous theorem, we can assert that the embedding of this cyclic subgroup into the center of the centralizer will be a quasi-isometric embedding. Since the centralizer of an element is a quasi-convex subgroup, it follows that this embedding retains the property of being quasi-isometric.

Thus, we have demonstrated that this infinite cyclic subgroup is quasi-isometrically embedded in the hyperbolic group G . Therefore, we can confidently state that the map from Z to G , defined by $n \mapsto g^n$, is indeed a quasi-isometric embedding. Our next objective is to prove that this infinite subgroup has finite index within the centralizer.

(Refer Slide Time: 29:39)

Proof of (iii). First we show that if $g^t = t g^{-1} t^{-1}$
 then $|p| = |q|$
 Suppose $t^{-1} g^k t = g^q \Rightarrow t^{-1} g^{mk} t = g^{mq}$
 The embeddings $\mathbb{Z} \rightarrow G$ & $\mathbb{Z} \rightarrow G$
 $m \mapsto g^{mq}$ $m \mapsto t^{-1} g^{mk} t$
 are quasi-isometric embeddings.
 Also, note that $t^{-m} g^k t^m = g^{q^m}$
 Let $|q| > |p|$.
 There exists $k \geq 1, c \geq 0$ s.t
 $\frac{1}{k} |q|^m - c \leq d(1, g^{q^m}) \leq 2md(1, t) + d(1, g^k)$
 $\leq 2md(1, t) + k|p|^m + c$
 $\Rightarrow \frac{1}{k} |q|^m - k|p|^m \leq 2md(1, t) + 2c$

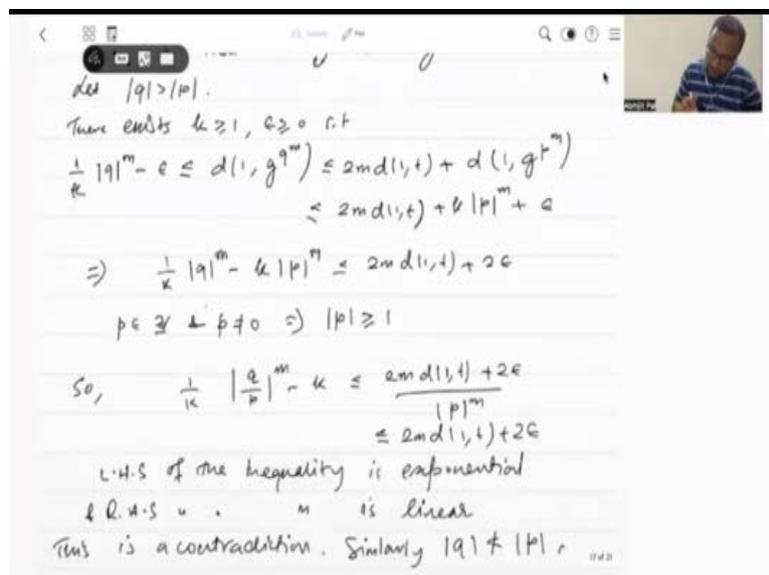

Let's begin by demonstrating the following relationship: if g^t is equal to the conjugate $t g^q t^{-1}$, then the absolute value of p is equal to the absolute value of q .

Now, suppose we have $t^{-1} g^p t = g^q$. This implies that $t^{-1} g^m p t = g^m q$. As we established earlier, these embeddings are indeed quasi-isometric embeddings, which we have already proven.

Additionally, consider the equation $t^{-m} g^p t^m = g^{q^m}$. This is a crucial observation and is presented as an exercise for further exploration.

Now, let's assume that the absolute value of q is strictly greater than the absolute value of p . This assumption will guide our subsequent analysis.

(Refer Slide Time: 30:56)

Let's delve into our findings. We can identify constants k greater than or equal to 1 and ϵ greater than or equal to 0, such that

$$\frac{1}{k} |q^m| - \epsilon \leq d(1, g^{q^m}) \leq 2m (d(1, t) + d(1, g^{p^m})).$$

This expression can further be refined to

$$\leq 2m(d(1, t) + k|p^m| + \epsilon).$$

This inequality arises from the fact that the embedding is a k, ϵ -quasi-isometric

embedding.

Now, let's analyze the next inequality. We have $g^{q^m} = t^{-m} g^{b^m} p^m$. Therefore, the distance from 1 to g^{q^m} can be assessed as being less than or equal to the length of this word, which corresponds to the aforementioned expression.

Next, the distance from 1 to g^{p^m} satisfies

$$d(1, g^{p^m}) \leq k|p^m| + \epsilon.$$

This conclusion follows from our earlier discussion regarding the quasi-isometric embedding of the map from Z to G , where m is mapped to g^{p^m} .

Now, consolidating all of this, we find that

$$\frac{1}{k}|q^m| - k|p^m| \leq 2m(d(1, t) + 2\epsilon).$$

It's important to note that p belongs to Z and that p_0 is equal to 0. This implies that $|p| \geq 1$.

From this, we can derive that

$$\frac{1}{k}|q|^m - k \leq 2m(d(1, t) + 2\epsilon).$$

Given that $|p| \geq 1$, the left-hand side of this inequality represents an exponential growth, while the right-hand side exhibits linear growth. This leads to a contradiction, as we initially assumed $|q| > |p|$.

Consequently, we can conclude that $|p|$ cannot be less than or equal to $|q|$. Thus, the only viable outcome is that $|p| = |q|$, which we have successfully demonstrated.

This leads us to an important conclusion: the positive powers of g belong to distinct conjugacy classes. We have demonstrated that if $g^p = t g^q t^{-1}$, it necessarily follows that $|p| = |q|$. Now, if we consider p and q as positive integers, and if they are distinct, this means that g^p and g^q cannot be conjugate to one another. Hence, we can conclude that the positive powers of g are indeed contained in distinct conjugacy classes.

index of the cyclic subgroup generated by g is finite in the centralizer of the element g .

Suppose, for the sake of contradiction, that this claim is not true. This means there exists an element x in the centralizer such that the distance from x to the cyclic subgroup is strictly greater than $2 \times \text{distance}(1, g) + 4\delta$. Let's denote this quantity as k . Thus, the distance between x and the cyclic subgroup equals the distance between 1 and x^{-1} in the group generated by g .

Consequently, there must exist an element y in the subgroup generated by g such that the distance from 1 to y equals this value. Since x is in the centralizer, and g also lies in the centralizer of the element g , it follows that y must also belong to the centralizer of g . In other words, x is in the centralizer of g and y is in the subgroup generated by g .

As a result, y will commute with g , meaning that $yg = gy$. Now, consider the following arrangement: connect the points 1 to y with a geodesic, and connect 1 to g with another geodesic. Additionally, connect the points y and gy with a geodesic. Since $gy = yg$, the length of this geodesic is equivalent to the length of the geodesic joining 1 and y because g commutes with y .

Furthermore, we have chosen y such that the distance from 1 to y exceeds k . Hence, we can take two points p and q that belong to the geodesic connecting 1 and y such that the distance from 1 to p is $\frac{k}{2}$ and the distance from q to y is also $\frac{k}{2}$.

Now, let's consider the point y_t to be the midpoint connecting p and q . We will also define the distance between y and y_t as t . Now, observe that there exists a point $g y_t$ on the geodesic connecting g and $g y$ such that the distance from y_t to $g y_t$ is less than or equal to 2δ .

How can we demonstrate this? We can connect the points 1 and $g y$ with a geodesic. If we take the point y_t , we will find either a point here or there such that the distance from y to this point is less than or equal to δ . We are considering the triangle formed by the points 1 , y , and $g y$, which we know to be δ -slim. Therefore, either this distance will be less than or equal to δ , or the other distance will be less than or equal to δ .

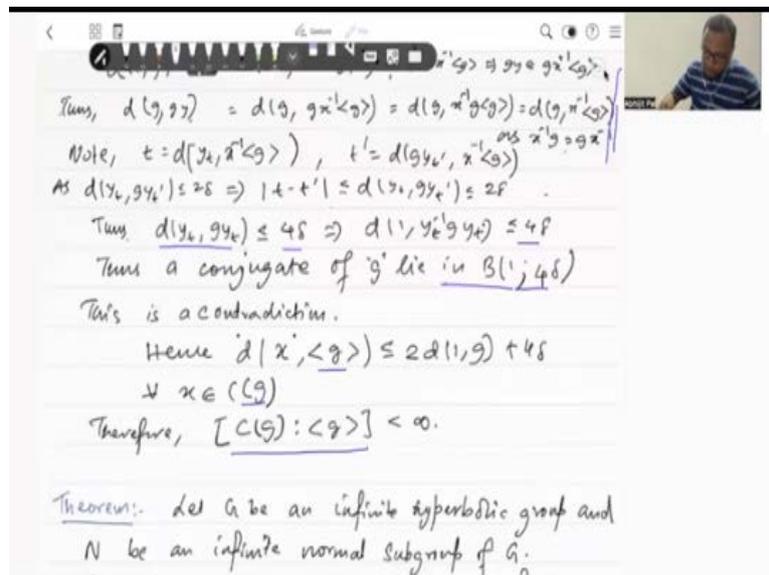

Now, suppose the distance is indeed less than or equal to δ . In that case, the distance between y_t and y will be less than δ plus the distance between y and g . Thus, the distance

between y and y_t will be less than $k/2$, where k is defined as twice the distance from 1 to g plus 4δ . When we take $k/2$, we find that $k/2$ equals the distance from 1 to g plus 2δ . This leads us to a contradiction.

Therefore, we conclude that if the distance from y_t to the side is less than or equal to δ , we will still find a point such that the distance is less than or equal to δ . By similar reasoning, there will also exist a point here, which we will refer to as $g y_t'$, and the distance will again be less than or equal to δ .

Hence, we find that there exists a point $g y_t'$ on the geodesic joining g and $g y_t$ such that the distance between y_t and $g y_t'$ is less than or equal to 2δ . Additionally, observe that the distance between y and y_t' will equal t' . Consequently, the distance between g and $g y_t'$ is equal to t' . Thus, we can conclude that the distance between y_t and y_t' is equal to t' .

(Refer Slide Time: 43:30)

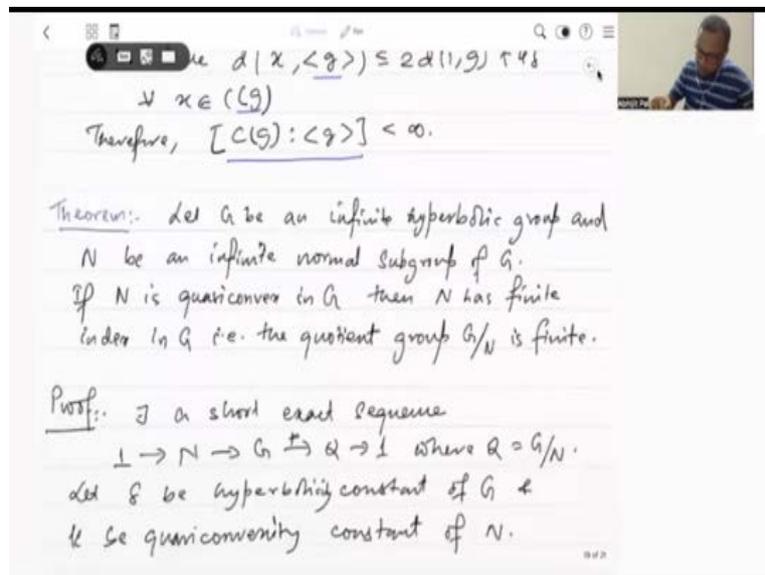

Now, let's revisit our findings. From our earlier discussion, we can demonstrate that the distance between y_t and $g y_t$ is less than or equal to 4δ . I won't go through the calculations again, but I have indicated the reasoning here. This implies that the distance between $y_t^{-1} g y_t$ is also less than or equal to 4δ . Consequently, this means that a conjugate of g lies within the ball of radius 4δ centered at 1 .

However, this presents a contradiction. We initially assumed that any conjugate of g

does not belong to this ball. Therefore, we conclude that the distance from x to this cyclic subgroup must be less than or equal to twice the distance from 1 to g plus 4δ . This relationship holds true for all x that belongs to the centralizer of the element g . As a result, we can infer that the index of this subgroup is indeed finite.

(Refer Slide Time: 45:03)

The next theorem states an important result, and while I won't go through the proof in detail, I encourage you to read it as it is provided here. The theorem asserts that if we take an infinite hyperbolic group G and an infinite normal subgroup N of G , and if N is quasi-convex in G , then N must have finite index in G . In simpler terms, this means that the quotient group G/N is a finite group. The proof of this theorem is documented here for your review. Okay, so I will stop here.
