Neumann Series and Resolvent Kernels II

Hello friends I welcome you to my second lecture on Neumann series and resolvent kernel. In the last lecture we discussed one problem on the solution of Volterra integral equation of second kind by finding the resolvent kernel. Here I start the one more such example to make things more clear. Let us consider the equation $y(x) = 1 + x^2 + \int_0^x \frac{1+x^2}{1+t^2} y(t) dt$.

You can see that it is a Volterra integral equation of the second kind. And so we will solve this equation by first finding the resolvent kernel and then determining the solution of this integral equation.

(Refer Slide Time: 01:07)

Example: Find the resolvent kernel for the Volterra-type integral equation

$$y(x) = (1 + x^2) + \int_0^x \left(\frac{1+x^2}{1+t^2} \right) y(t) dt.$$

and hence determine its solution.

Solution: The resolvent kernel for given integral equation

$$R(x, t; \lambda) = \left(\frac{1+x^2}{1+t^2} \right) e^{-\lambda t}$$

and the solution of the given integral equation is

$$y(x) = (1 + x^2) e^x.$$

So let us write we will first find the iterated kernels. Let us recall that the iterated kernels $K_1(x, t)$ is given by $K(x, t)$ and we are given here $K(x, t) = \frac{1+x^2}{1+t^2}$. The kernel of the integral equation is $K(x, t)$ which is given as $\frac{1+x^2}{1+t^2}$. Then $K_2(x, t)$, we know that $K_2(x, t)$ is given by $\int_t^x K(x, z) K_1(z, t) dz$.

So we can write it as $\int_t^x K(x, z) K_1(z, t) dz$. $K(x, z)$ will be $\frac{1+x^2}{1+z^2}$ upon $\frac{1+z^2}{1+t^2}$ into $K_1(z, t)$, $K_1(z, t)$ is same as $K(z, t)$ and $K(z, t)$ will be $\frac{1+z^2}{1+t^2}$ divided by $1+t^2$.

square into $d z$. So $1 + z^2$ will cancel with $1 + z^2$ and $1 + x^2$ by $1 + t^2$ is independent of z , so we can write it outside. And what we get is $\int_t^x \frac{1 + x^2}{1 + t^2} dz$ which after integration gives us $\frac{1 + x^2}{1 + t^2} (x - t)$. So thus we have obtained the second iterated kernel $K_2(x, t)$. Let us find $K_3(x, t)$ also in a similar manner.

So $K_3(x, t)$ is given by $\int_t^x K_2(x, z) K_2(z, t) dz$. This is equal to $\int_t^x \frac{1 + x^2}{1 + z^2} \frac{1 + z^2}{1 + t^2} dz$. $K_2(x, z)$ is $\frac{1 + x^2}{1 + z^2}$ and $K_2(z, t)$ is $\frac{1 + z^2}{1 + t^2}$, so $K_2(x, t)$ is this when we replace x by z we get $K_2(z, t)$. So $1 + z^2$ divided by $1 + t^2$ into $z - t$ dz . So again we will cancel this and we will have $\frac{1 + x^2}{1 + t^2} \int_t^x (z - t) dz$. After integration here what we have is $\frac{1 + x^2}{1 + t^2} \frac{(z - t)^2}{2}$ and then $z - t$ whole square by 2.

The evaluation of this will give us $\frac{1 + x^2}{1 + t^2} \frac{(x - t)^2}{2}$ which we can write as $\frac{(x - t)^2}{2!}$.

(Refer Slide Time: 04:51)

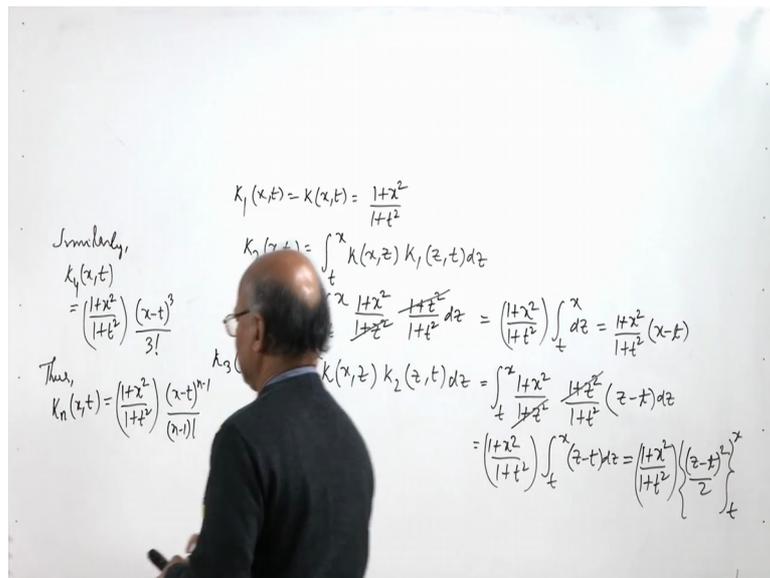

$$K_1(x, t) = \frac{1+x^2}{1+t^2}$$

$$K_2(x, t) = \int_t^x \frac{1+x^2}{1+z^2} \frac{1+z^2}{1+t^2} dz = \frac{1+x^2}{1+t^2} \int_t^x dz = \frac{1+x^2}{1+t^2} (x-t)$$

$$K_3(x, t) = \int_t^x \frac{1+x^2}{1+z^2} \frac{1+z^2}{1+t^2} (z-t) dz = \frac{1+x^2}{1+t^2} \int_t^x (z-t) dz = \frac{1+x^2}{1+t^2} \left. \frac{(z-t)^2}{2} \right|_t^x = \frac{1+x^2}{1+t^2} \frac{(x-t)^2}{2!}$$

You can continue this process. You can find $K_4(x, t)$ similarly. You can see that it comes out to be $\frac{1 + x^2}{1 + t^2} \frac{(x - t)^3}{3!}$. So generalizing we have thus $K_n(x, t)$ is equal to $\frac{1 + x^2}{1 + t^2} \frac{(x - t)^{n-1}}{(n-1)!}$.

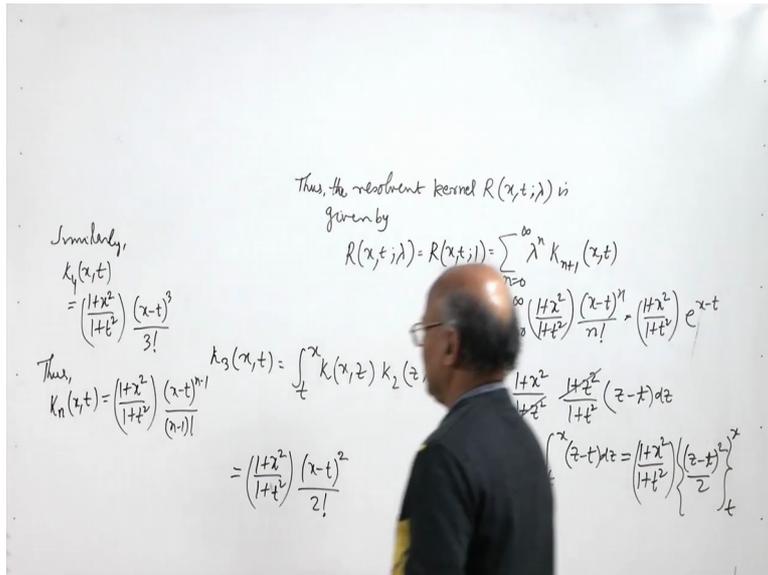

(Refer Slide Time: 05:44)

Now let us find the resolvent kernel $R(x,t)$. So thus the resolvent kernel is, now you can see in the given integral equation λ is equal to 1 so we have $R(x,t)$ equal to $\sum_{n=0}^{\infty} \lambda^n K_n(x,t)$. So this is λ is 1 here, so summation n equal to 0 to infinity and then we have 1 to the power n then K_{n+1} will be $\frac{1+x^2}{1+t^2} \frac{(x-t)^n}{n!}$.

And this is nothing but $\frac{1+x^2}{1+t^2} e^{x-t}$. $\sum_{n=0}^{\infty} \frac{(x-t)^n}{n!}$ is e^{x-t} .

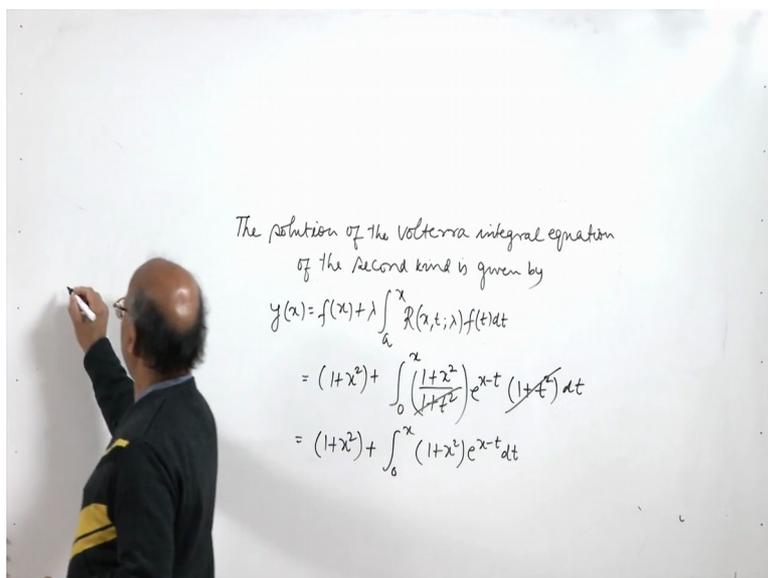

(Refer Slide Time: 07:21)

Now having found $R(x,t;\lambda)$ so now let us find the solution of the given integral equation. So let us put the value of $R(x,t;\lambda)$. Here the solution of the integral equation is given by Volterra integral equation of the second kind $y(x) = f(x) + \lambda \int_a^x R(x,t;\lambda) f(t) dt$. So let us put the values here, $f(x)$ is equal to $1+x^2$, λ is equal to 1, a is given to be equal to 0, so 0 to x and $R(x,t;\lambda)$ we have found $1+x^2$ by $1+t^2$ into e^{-x-t} .

And then we have $f(t)$ is $1+t^2$, dt . So what we get is $1+x^2$, $f(t)$ is $1+t^2$ square. So this $1+t^2$ square and the $1+t^2$ square here will get cancelled and we will have $1+x^2$, $\int_0^x (1+x^2) e^{-x-t} dt$.

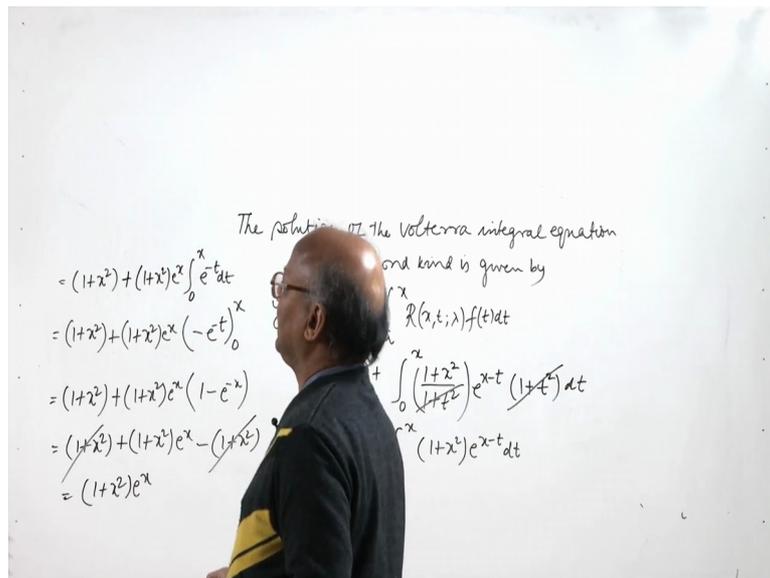

(Refer Slide Time: 09:50)

And this can be written further as $1 + x^2$, $1 + x^2$ into e to the power x we can write outside and we have to simply integrate 0 to x , e to the power minus t , $d t$. So what we get is $1 + x^2$ plus $1 + x^2$, e to the power x and minus e to the power minus t integral 0 to x . So we have $1 + x^2$, $1 + x^2$, e to the power x and then we have $1 - e$ to the power minus x .

So what we have is these two cancel and we have. So $y(x)$ is equal to $1 + x^2$ into e to the power x is the solution of the given integral equation.

(Refer Slide Time: 11:10)

Now let us discuss how to find the solution of a Volterra integral equation of second kind when its kernel we take as $K(x, t)$. Kernel $K(x, t)$ is of a particular form. Let us say this is the equation. $Y(x)$ is equal to $f(x)$ plus λ times $a(x)$, $K(x, t) y(t) dt$ and the kernel $K(x, t)$ is a polynomial of degree $n-1$ in t . So that we can always write it in the form $K(x, t) = a_0 + a_1 x + \dots + a_{n-1} x^{n-1} t^{n-1}$ and so on a $n-1$ over $n-1$ factorial, $x^{n-1} t^{n-1}$ to the power $n-1$.

You can see that this since we have assumed $K(x, t)$ to be a polynomial in t of degree $n-1$ we can always write it in this form where (\max) it is a polynomial in t of degree $n-1$.

(Refer Slide Time: 12:04)

and the coefficients $a_k(x)$, $k = 0, 1, 2, \dots, (n-1)$ are continuous in $a \leq x \leq b$.
 Then, the resolvent kernel $R(x, t; \lambda)$ of (1) is given by

$$R(x, t; \lambda) = \frac{1}{\lambda} \frac{d^n}{dx^n} g(x, t; \lambda)$$

where $g(x, t; \lambda)$ is a solution of the differential equation

$$\frac{d^n g}{dx^n} - \lambda \left[a_0(x) \frac{d^{n-1} g}{dx^{n-1}} + a_1(x) \frac{d^{n-2} g}{dx^{n-2}} + \dots + a_{n-1}(x) g \right] = 0,$$

Now the coefficients $a_k(x)$, $k = 0, 1, 2, \dots, (n-1)$ are continuous in the close interval $a \leq x \leq b$. Then in this case in terms of that the resolvent kernel $R(x, t; \lambda)$ is given by $\frac{1}{\lambda} \frac{d^n}{dx^n} g(x, t; \lambda)$. And $g(x, t; \lambda)$ is a solution of this differential equation of n th order.

So $\frac{d^n g}{dx^n} - \lambda [a_0(x) \frac{d^{n-1} g}{dx^{n-1}} + a_1(x) \frac{d^{n-2} g}{dx^{n-2}} + \dots + a_{n-1}(x) g] = 0$. This is n th order differential equation with variable coefficients.

(Refer Slide Time: 12:49)

and the coefficients $a_k(x)$, $k = 0, 1, 2, \dots, (n-1)$ are continuous in $a \leq x \leq b$.
Then, the resolvent kernel $R(x, t; \lambda)$ of (1) is given by

$$R(x, t; \lambda) = \frac{1}{\lambda} \frac{d^n}{dx^n} g(x, t; \lambda)$$

where $g(x, t; \lambda)$ is a solution of the differential equation

$$\frac{d^n g}{dx^n} - \lambda \left[a_0(x) \frac{d^{n-1} g}{dx^{n-1}} + a_1(x) \frac{d^{n-2} g}{dx^{n-2}} + \dots + a_{n-1}(x) g \right] = 0 ,$$

BIT ROORKEE NPTEL ONLINE CERTIFICATION COURSE 4

And the conditions on g are g at x equal to t is 0. The $\frac{d g}{dx}$ at x equal to t is also 0 and n minus 2th derivative of g with respect to x at x equal to t is 0. While n minus 1th derivative of g with respect to x at x equal to t is 1.

And then the required solution is given by $y(x) = f(x) + \lambda \int_a^x R(x, t; \lambda) f(t) dt$ as usual. As we have earlier seen how to find the solution once the resolvent kernel is known. So by putting the value of the resolvent kernel $R(x, t; \lambda)$ here we can then find the required solution of the given integral equation.

(Refer Slide Time: 13:35)

satisfying the conditions

$$g|_{x=t} = \frac{dg}{dx}|_{x=t} = \dots = \frac{d^{n-2}g}{dx^{n-2}}|_{x=t} = 0; \frac{d^{n-1}g}{dx^{n-1}}|_{x=t} = 1.$$

Then the required solution is given by

$$y(x) = f(x) + \lambda \int_a^x R(x,t; \lambda) f(t) dt.$$

5

Now let us see how this method works by taking a little example. So let us say $y(x)$ is equal to $1 - 2x - 4x^2$ and we have $\int_0^x (3 + 6t - 4t^2) y(t) dt$. So here you can see that $f(x)$ function is $1 - 2x - 4x^2$, λ is equal to 1, the lower limit a is equal to 0 and $K(x,t)$ is $3 + 6t - 4t^2$ which is a polynomial in t of degree 2.

And already it is written in the form in which we want $K(x,t)$ to be. So we want $K(x,t)$ to be in the form $a_0 + a_1(x-t) + a_2(x-t)^2$ by 2 factorial. It is in that form already. So here $f(x)$ is this, λ is 1, $K(x,t)$ is $3 + 6t - 4t^2$. So let us compare this form of $K(x,t)$ with the general form of $K(x,t)$ when it is a polynomial in t of degree 2. So you can see that when we compare a_0 is equal to 3, a_1 is equal to 6 and a_2 is equal to minus 8, okay.

(Refer Slide Time: 14:53)

Example: Find the resolvent kernel for the integral equation

$$y(x) = (1 - 2x - 4x^2) + \int_0^x \{3 + 6(x-t) - 4(x-t)^2\} y(t) dt.$$

Solution: Here $f(x) = 1 - 2x - 4x^2$, $\lambda = 1$ and $K(x, t) = 3 + 6(x-t) - 4(x-t)^2$.

Let $K(x, t) = a_0(x) + a_1(x)(x-t) + a_2(x) \frac{(x-t)^2}{2!}$.

Comparing, we get

$$a_0(x) = 3, a_1(x) = 6, a_2(x) = -8.$$

6

Now $R(x, t, \lambda)$ will be $d^3 g(x, t, \lambda) / dx^3$. Why? Because here $K(x, t, \lambda)$ is a polynomial in t of degree 2. So when it is a polynomial in t of degree $n-1$, the n th order differential equation in g we have. So $R(x, t, \lambda)$ is $d^3 g(x, t, \lambda) / dx^3$ and λ is 1. So we can also write it as $d^3 g(x, t) / dx^3$.

Now this $g(x, t)$ is the solution of this differential equation. So this is the third order differential equation because n is equal to 3 here and we have put the values of a_0 , a_1 and a_2 . So $d^3 g / dx^3$ we seen that $a_0(x)$ is equal to 3, $a_1(x)$ is 6, $a_2(x)$ is minus 8. So substituting these values we get this third order differential equation with constant coefficients and we know how to solve n th order differential equation with constant coefficients.

So let us write it in the notation of D where D is the derivative with respect to x . So $D^3 g - 3D^2 g - 6Dg + 8g = 0$, this differential operator operates on g equal to 0. So it is a homogeneous differential equation of third order with constant coefficients. Now the conditions on g are $g = 0$ and $dg/dx = 0$ at $x = t$. And $d^2 g / dx^2 = 1$ at $x = t$, okay.

(Refer Slide Time: 16:26)

Also,

$$R(x, t; \lambda) = \frac{d^3 g(x, t; \lambda)}{dx^3} = \frac{d^3 g(x, t; 1)}{dx^3} \quad \text{as } \lambda = 1,$$

where $g(x, t; 1)$ satisfies the differential equation

$$\frac{d^3 g}{dx^3} - \left\{ 3 \frac{d^2 g}{dx^2} + 6 \frac{dg}{dx} - 8g \right\} = 0$$

or $(D^3 - 3D^2 - 6D + 8)g = 0, \quad D \equiv d/dx. \quad \dots(2)$

satisfying the conditions $g = 0, \frac{dg}{dx} = 0$ at $x = t$ and $\frac{d^2 g}{dx^2} = 1$ at $x = t. \quad \dots(3)$

7

Now we can write the auxiliary equation corresponding to this homogeneous equation. So auxiliary equation is $m^3 - 3m^2 - 6m + 8 = 0$ and you can check that m is equal to 1, -2, 4. They are the values of m which satisfies this equation. Now since these three values are real and distinct the solution of this third order differential equation in g is written as $g = A e^{mx} + B e^{-2x} + C e^{4x}$.

Now in order to use the conditions on g let us differentiate it with respect to x . So we get $\frac{dg}{dx} = A e^{mx} - 2B e^{-2x} + 4C e^{4x}$ and we get $\frac{d^2 g}{dx^2} = A m^2 e^{mx} + 4B e^{-2x} + 16C e^{4x}$. And when we differentiate it once more we get $\frac{d^3 g}{dx^3} = A m^3 e^{mx} - 8B e^{-2x} + 64C e^{4x}$.

(Refer Slide Time: 17:25)

The auxiliary equation of (2) is given by

$$m^3 - 3m^2 - 6m + 8 = 0,$$
$$m = 1, -2, 4.$$

Therefore

$$g = Ae^x + Be^{-2x} + Ce^{4x}$$
$$\frac{dg}{dx} = Ae^x - 2Be^{-2x} + 4Ce^{4x}$$
$$\frac{d^2g}{dx^2} = Ae^x + 4Be^{-2x} + 16Ce^{4x}$$

8

Now let us use the conditions on g . When you will use the conditions on g , the conditions on g are at x equal to t , g is 0, $\frac{dg}{dx}$ at x equal to 0 and at x equal to t second derivative is 1. If you use these three conditions on this 3 equations, okay, we shall arrive at the three equations in A, B, C . Solving those three linear equations in A, B, C we get the values of A, B, C .

(Refer Slide Time: 17:57)

The auxiliary equation of (2) is given by

$$m^3 - 3m^2 - 6m + 8 = 0,$$
$$m = 1, -2, 4.$$

Therefore

$$g = Ae^x + Be^{-2x} + Ce^{4x}$$
$$\frac{dg}{dx} = Ae^x - 2Be^{-2x} + 4Ce^{4x}$$
$$\frac{d^2g}{dx^2} = Ae^x + 4Be^{-2x} + 16Ce^{4x}$$

8

And the values of A, B, C when we put in the expression of $g(x, t)$ we get here the following expression of $g(x, t)$. $g(x, t)$ is equal to $-\frac{1}{9}e^{x-t} + \frac{1}{18}e^{-2x+2t} + \frac{1}{18}e^{4x-4t}$. Now we differentiate it once, okay.

So we get (deja) g dash, in order to find why we are differentiating now because we want to know what is the $R \times t$ lambda? We want to know $R \times t$ lambda and for $R \times t$ lambda we need to know what is $g \times t$ 1 over $d \times$ cube? So we have already found $g \times t$ 1, so we will differentiate it thrice and get $R \times t$ lambda.

(Refer Slide Time: 18:42)

Also,

$$R(x,t;\lambda) = \frac{d^3 g(x,t;\lambda)}{dx^3} = \frac{d^3 g(x,t;1)}{dx^3} \quad \text{as } \lambda = 1,$$

where $g(x,t;1)$ satisfies the differential equation

$$\frac{d^3 g}{dx^3} - \left\{ 3 \frac{d^2 g}{dx^2} + 6 \frac{dg}{dx} - 8g \right\} = 0$$

or $(D^3 - 3D^2 - 6D + 8)g = 0, \quad D \equiv d/dx. \quad \dots(2)$

satisfying the conditions $g=0, \frac{dg}{dx}=0$ at $x=t$ and $\frac{d^2 g}{dx^2}=1$ at $x=t. \quad \dots(3)$

7

So $g \times t$ 1 is this that is differentiated once. We get this expression. We differentiate it again, we get this expression and when we differentiate it again we get this expression. So this is third derivative of $g \times t$ 1 and what we get is this.

(Refer Slide Time: 19:02)

Using the given conditions on g , we have

$$g(x,t;1) = -\frac{1}{9}e^{x-t} + \frac{1}{18}e^{-2x+2t} + \frac{1}{18}e^{4x-4t}$$

Now, we differentiate it thrice w. r. t. x , we have

$$g'(x,t;1) = -\frac{1}{9}e^{x-t} - \frac{1}{9}e^{-2x+2t} + \frac{2}{9}e^{4x-4t}$$

$$g''(x,t;1) = -\frac{1}{9}e^{x-t} + \frac{2}{9}e^{-2x+2t} + \frac{8}{9}e^{4x-4t}$$

$$g'''(x,t;1) = -\frac{1}{9}e^{x-t} - \frac{4}{9}e^{-2x+2t} + \frac{32}{9}e^{4x-4t}.$$

9

Now so this is nothing but we get $R(x,t)$. $R(x,t)$ is third derivative of $g(x,t)$. So with respect to x , so $y(x)$ is equal to $f(x)$ plus integral from 0 to x of $R(x,t)$ into $f(t) dt$. $f(t)$ is $1 - 2t - 4t^2$. And we put the value of $R(x,t)$ here. Now you can do the integration by parts here by simply taking e to the power x here outside in the first case. In the second you can take e to the power $2x$ out. In the third integral you can take e to the power $4x$ outside and then you integrate by parts.

Say for example in the first case you will have to integrate e to the power $x - t$ into $1 - 2t - 4t^2$ with respect to t and put the limits 0 to x . In the second case we will be integrating e to the power $2x - 2t$ into $1 - 2t - 4t^2$ with respect to t and then (pu) we put the limits. And here we will be integrating e to the power $4x - 4t$ into $1 - 2t - 4t^2$ and put the limits. So after you integrate by parts these three terms and substitute the limits and simplify you will get $y(x)$ equal to e^x .

(Refer Slide Time: 20:22)

Hence, the required solution is

$$y(x) = (1 - 2x - 4x^2) + \int_0^x R(x,t)(1 - 2t - 4t^2) dt.$$

$$= (1 - 2x - 4x^2) + \int_0^x \left\{ -\frac{1}{9} e^{x-t} - \frac{4}{9} e^{-2(x-t)} + \frac{32}{9} e^{4(x-t)} \right\} (1 - 2t - 4t^2) dt.$$

Solving, we get $y(x) = e^x$.

NPTEL ONLINE CERTIFICATION COURSE

Now let me tell you that this method you can see is very cumbersome. You have to first find the differential equation in g , then you have to solve the differential equation in g . The differential equation in g has variable coefficients. Their functions depending on x and when we have variable coefficient it is not easy to solve the differential equation. Here what happened that the coefficients of the differential equation in g turned out to be constant so we could easily solve this differential equation.

And then we use the conditions over g to determine $g(x,t)$. And once we determined $g(x,t)$ we have to differentiate say for example in this case three times to arrive at $R(x,t)$.

lambda and then we (diff) integrate R x t lambda. And then we put the value of R x t lambda in this equation and integrate which is again a lengthy procedure. So if you solve this by using the Laplace transform technique, let us say for example this one.

(Refer Slide Time: 21:32)

Example: Find the resolvent kernel for the integral equation

$$y(x) = (1 - 2x - 4x^2) + \int_0^x \{3 + 6(x-t) - 4(x-t)^2\} y(t) dt.$$

Solution: Here $f(x) = 1 - 2x - 4x^2$, $\lambda = 1$ and $K(x, t) = 3 + 6(x-t) - 4(x-t)^2$.

Let $K(x, t) = a_0(x) + a_1(x)(x-t) + a_2(x) \frac{(x-t)^2}{2!}$.

Comparing, we get

$$a_0(x) = 3, a_1(x) = 6, a_2(x) = -8.$$

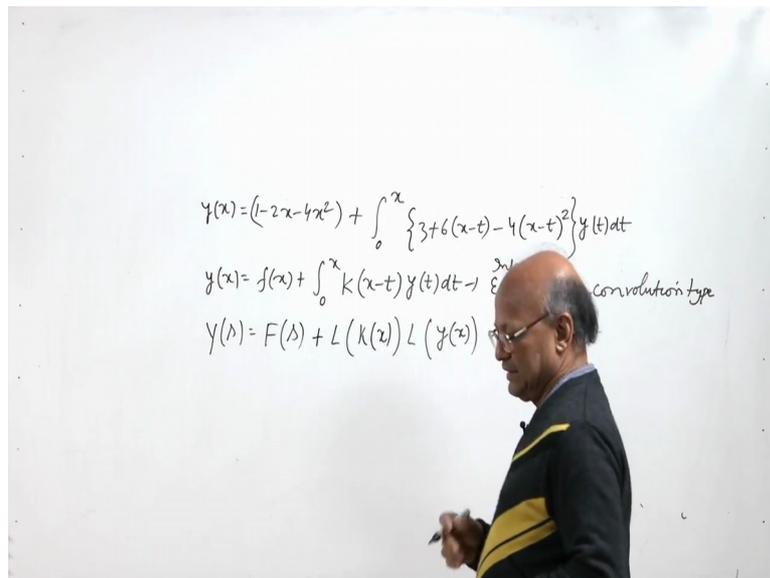

6

This integral equation let us solve by using the Laplace transform technique. What we will do? We have y x equal to 1 minus 2 x minus 4 x square integral 0 to x and then we have 3 plus 6 times x minus t minus 4 times x minus t whole square, y t d t. So you can compare this equation with y x equal to f x plus integral 0 to x, K x minus t, y t d t. This equation is of this form. And such equations are called as (conver) integral equations of (convo) convolution type.

We shall be later on discussing how to find the solution of integral equation of convolution type. What we do is we take the Laplace transform of both sides. Suppose we assume that Laplace transform y x is y s and then the Laplace transform of f x is f s, then we get y s equal to f s and then Laplace transform of this. Laplace transform of this integral 0 to x, K x minus t, y t d t can be found by using the convolution theorem and we get Laplace transform of say K x into Laplace transform of y x.

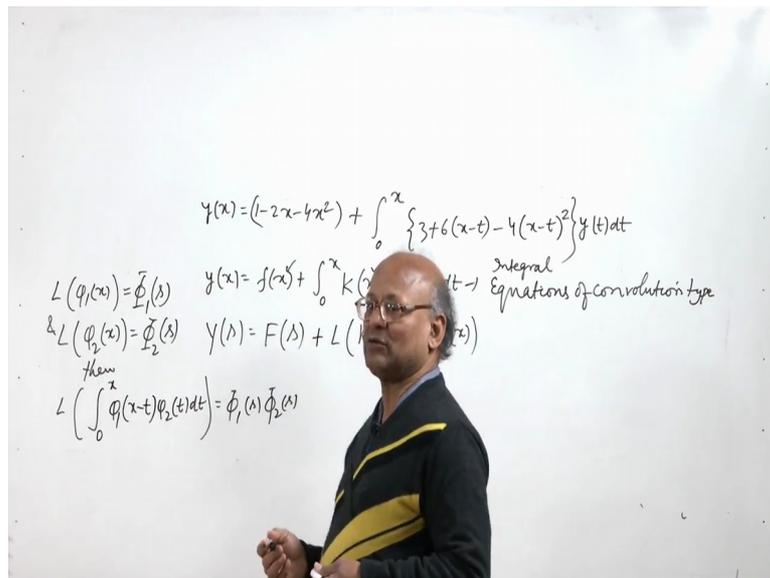

(Refer Slide Time: 23:40)

Because in the convolution theorem we say that if the Laplace transform of two functions $\phi_1(x)$ and $\phi_2(x)$ exist, Laplace transform of $\phi_1(x)$ is say $\phi_1(s)$ and Laplace transform of $\phi_2(x)$ is $\phi_2(s)$ then the Laplace transform of their convolution is defined as say 0 to x . We can say $\phi_1(x-t)$ into $\phi_2(t) dt$ is equal to $\phi_1(s)$ into $\phi_2(s)$. So here we see that we have the convolution of two functions $K(x)$ and $y(x)$ here.

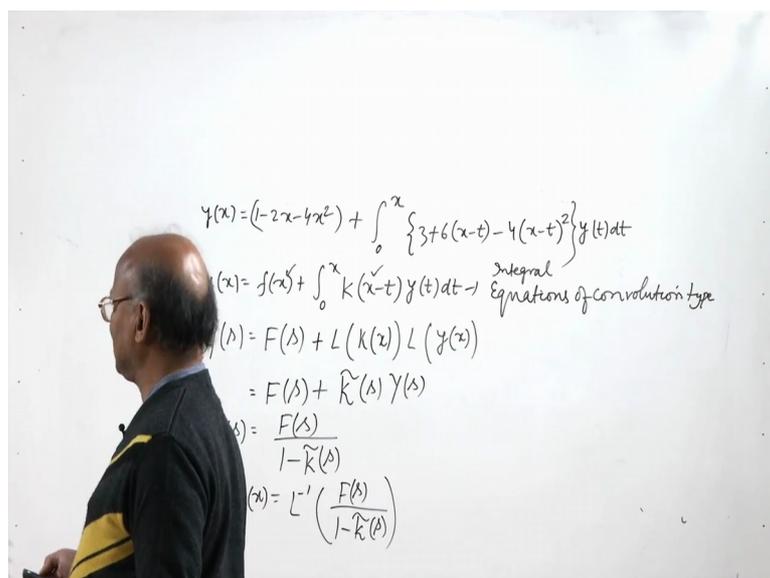

And so while taking the Laplace transform of this we have written it as the product of Laplace transform of $K(x)$ into Laplace transform of $y(x)$. But here we need to assume that the functions $K(x)$ and $f(x)$, the functions $f(x)$ and $K(x)$ are such that their Laplace transform exist. That means they are of exponential order. So once we assume that then it turns out that the function $y(x)$ is also of exponential order and so we can write it as Laplace transform.

(Refer Slide Time: 25:03)

So once we have this I can write this further as and then we can solve it for y s. Y s will be equal to F s divided by 1 minus this. And after we have found y s we can take the inverse Laplace transform. So then y x, the solution of the given integral equation is then L inverse of F s over 1 minus this. And you will see that we can easily find the solution of this differential equation which was given by y x equal to e to the power x if we apply this technique. And it can be obtained in just 5-6 steps.

(Refer Slide Time: 26:19)

Here this is a very cumbersome method to find the solution of the integral equation. But it is a method which is purely of academic interest. But here we can assume this to be a

polynomial of any degree and that can be managed here also. So one can always use to find the solution of such an integral equation by applying the technique of integral equations of convolution type.

(Refer Slide Time: 26:51)

Example: Find the resolvent kernel for the integral equation

$$y(x) = (1 - 2x - 4x^2) + \int_0^x \{3 + 6(x-t) - 4(x-t)^2\} y(t) dt.$$

Solution: Here $f(x) = 1 - 2x - 4x^2$, $\lambda = 1$ and $K(x, t) = 3 + 6(x-t) - 4(x-t)^2$.

Let $K(x, t) = a_0(x) + a_1(x)(x-t) + a_2(x) \frac{(x-t)^2}{2!}$.

Comparing, we get

$$a_0(x) = 3, a_1(x) = 6, a_2(x) = -8.$$

BIT ROORKEE NPTEL ONLINE CERTIFICATION COURSE 6

Now let us see there is another case you here. Suppose the kernel $K(x, t)$ is a polynomial of degree $n - 1$ in x then we can (rep) always represent it as $K(x, t) = b_0(t) + b_1(t)(t-x) + \dots + \frac{b_{n-1}(t)}{(n-1)!} (t-x)^{n-1}$. You can see it is a polynomial in x of degree $n - 1$.

(Refer Slide Time: 27:21)

Particular form II : Suppose that the kernel $K(x, t)$ is a polynomial of degree $(n - 1)$ in x , then we can represent it as

$$K(x, t) = b_0(t) + b_1(t)(t-x) + \dots + \frac{b_{n-1}(t)}{(n-1)!} (t-x)^{n-1}. \quad \dots(3)$$

Then the resolvent kernel $R(x, t; \lambda)$ of (1) is given by

$$R(x, t; \lambda) = -\frac{1}{\lambda} \frac{d^n}{dt^n} h(x, t; \lambda)$$

where $h(x, t; \lambda)$ is a solution of the differential equation

BIT ROORKEE NPTEL ONLINE CERTIFICATION COURSE 11

Now then the resolvent kernel $R(x, t; \lambda)$ of the Volterra integral equation 1 is given by $R(x, t; \lambda)$ is equal to $-\frac{1}{\lambda} \frac{d^n}{dt^n} h(x, t; \lambda)$ where $h(x, t; \lambda)$ is a solution of the differential equation of n th order with variable coefficients.

(Refer Slide Time: 27:49)

Particular form II : Suppose that the kernel $K(x, t)$ is a polynomial of degree $(n-1)$ in x , then we can represent it as

$$K(x, t) = b_0(t) + b_1(t)(t-x) + \dots + \frac{b_{n-1}(t)}{(n-1)!} (t-x)^{n-1}. \quad \dots(3)$$

Then the resolvent kernel $R(x, t; \lambda)$ of (1) is given by

$$R(x, t; \lambda) = -\frac{1}{\lambda} \frac{d^n}{dt^n} h(x, t; \lambda)$$

where $h(x, t; \lambda)$ is a solution of the differential equation

Because b_0, b_1, b_{n-1} they depend on t . So this n th order differential equation homogeneous and it satisfies these conditions h at t equal to x , $\frac{dh}{dt}$ at t equal to x , $\frac{d^{n-2}h}{dt^{n-2}}$ at t equal to x is 0. And $n-1$ is a derivative of h with respect to t at t equals to x is 1. And then once we have these we can find the solution of this differential equation $h(x, t; \lambda)$.

(Refer Slide Time: 28:27)

$$\frac{d^n h}{dt^n} + \lambda \left[b_0(t) \frac{d^{n-1} h}{dt^{n-1}} + b_1(t) \frac{d^{n-2} h}{dt^{n-2}} + \dots + b_{n-1}(t) h \right] = 0,$$

satisfying the conditions

$$h \Big|_{t=x} = \frac{dh}{dt} \Big|_{t=x} = \dots = \frac{d^{n-2} h}{dt^{n-2}} \Big|_{t=x} = 0; \frac{d^{n-1} h}{dt^{n-1}} \Big|_{t=x} = 1.$$

The required solution is given by

$$y(x) = f(x) + \int_a^x R(x, t; \lambda) f(t) dt.$$

And once $h(x, t, \lambda)$ is known we can differentiate it n times and multiply by $-1/\lambda$ to get $R(x, t, \lambda)$. $R(x, t, \lambda)$ then is used here in this equation to determine the solution $y(x)$ of the given integral equation.

(Refer Slide Time: 28:43)

$$\frac{d^n h}{dt^n} + \lambda \left[b_0(t) \frac{d^{n-1} h}{dt^{n-1}} + b_1(t) \frac{d^{n-2} h}{dt^{n-2}} + \dots + b_{n-1}(t) h \right] = 0,$$
 satisfying the conditions

$$h \Big|_{t=x} = \frac{dh}{dt} \Big|_{t=x} = \dots = \frac{d^{n-2} h}{dt^{n-2}} \Big|_{t=x} = 0; \frac{d^{n-1} h}{dt^{n-1}} \Big|_{t=x} = 1.$$

The required solution is given by

$$y(x) = f(x) + \int_a^x R(x, t; \lambda) f(t) dt.$$

IIT ROORKEE NPTEL ONLINE CERTIFICATION COURSE 12

Now let us take an example on this. Suppose $y(x)$ is equal to $\cos x - x - 2$. So this is over function $f(x)$. You can see $f(x)$ is equal to $\cos x - x - 2$. λ is 1 here and $K(x, t)$ is a polynomial in x of degree 1. So it can be treated by the second particular form. You can also regard $K(x, t)$ here as a polynomial in t of degree 1. so it is of the form 1 as well as of the form 2.

So $K(x, t)$ is $t - x$ here. We assume $K(x, t)$ to be of the form $b_0 + b_1 t + b_2 t^2 + \dots$ because $K(x, t)$ we are assuming as a polynomial in x of degree 1 in x , so we can write it like this. And then we compare this given $K(x, t)$ with this standard form and then we see that b_0 is equal to 0 and b_1 is equal to 1. Resolvent kernel $R(x, t, \lambda)$ will become $R(x, t, 1)$ because λ is 1 here and it will be given by $-d^2 h(x, t) / dt^2$ because $K(x, t)$ is a polynomial in x of degree 1.

So we have second derivative. Now where $h(x, t)$ satisfies the second order differential equation $d^2 h / dt^2 + \lambda (b_0 + b_1 t) h = 0$. λ is equal to 1 here, b_0 is equal to 0 here, b_1 is equal to 1.

(Refer Slide Time: 30:11)

Example: Consider

$$y(x) = (\cos x - x - 2) + \int_a^x (t-x)y(t)dt.$$

Solution: Here $f(x) = \cos x - x - 2$, $\lambda=1$ and $K(x, t) = t - x$.
Let $K(x, t) = b_0(t) + b_1(t)(t - x)$ then $b_0(t) = 0$, $b_1(t) = 1$.
The resolvent kernel is given by

$$R(x, t; \lambda) = R(x, t; 1) = -\frac{d^2 h(x, t; 1)}{dt^2},$$

where $h(x, t; 1)$ satisfies the differential equation

$$\frac{d^2 h}{dt^2} + \lambda [b_0(t) + b_1(t)h] = 0$$

 IIT ROORKEE  NPTEL ONLINE CERTIFICATION COURSE 13

So this equation reduces to $d^2 h$ by $d t$ square plus h equal to 0. So this is the second order differential equation with constant coefficients. And the conditions imposed on h are h is equal to 0 at t equal to x and $d h$ by $d t$ equal to 1 at t equal to x . Now we know how to determine the solution of this differential equation with constant coefficients. So here we have the auxiliary equation $m^2 + 1 = 0$ which has got two roots, plus minus i . So we have the corresponding solution here as $h(x, t) = A \cos t + B \sin t$.

Now we will determine $d h$ by $d t$ here. So $-\sin t + B \cos t$, substitute t equal to x and put h is equal to 0 in this equation. And then put here t equal to x and put $d h$ by $d t$ equal to 1. Solve these two equations for the values of A and B . Substitute and then we will see that $h(x, t) = \sin t - x$, okay.

(Refer Slide Time: 31:15)

$$\frac{d^2h}{dt^2} + h = 0$$
 satisfying the conditions $h=0$ at $t=x$ and $\frac{dh}{dt} = 1$ at $t=x$.

$$\Rightarrow h(x, t; 1) = A \cos t + B \sin t$$

$$\frac{dh}{dt} = -A \sin t + B \cos t.$$

Using the given conditions on h, we get

$$h(x, t; 1) = \sin(t - x).$$

BIT ROORKEE NPTEL ONLINE CERTIFICATION COURSE 14

So then once we know $h(x, t; 1)$ we can then differentiate twice $h(x, t; 1)$ with respect to t multiplied by minus 1, we get $R(x, t; 1)$. So $R(x, t; 1)$ will be equal to $\sin t \cos x - \cos t \sin x$ and then $y(x)$ is equal to $\int_0^x (\sin t \cos x - \cos t \sin x) dt$. So you can integrate here. We can open this $\sin t \cos x - \cos t \sin x$ by the formula $\sin(A - B)$. You can open this and then you can integrate by parts. You can see that the answer is $y(x)$ is equal to $\sin x \cos x - \frac{1}{2} x \sin x$.

(Refer Slide Time: 32:06)

Hence the required solution is given by

$$y(x) = (\cos x - x - 2) + \int_0^x \sin(t - x)(\cos t - t - 2) dt$$

$$= -\cos x - \sin x - \frac{1}{2} x \sin x.$$

BIT ROORKEE NPTEL ONLINE CERTIFICATION COURSE 15

So what I would suggest that this is again this method is of purely academic interest. Otherwise we can always treat it as an integral equation of convolution type and by writing t

minus x as minus times x minus t. So it is an integral equation of convolution type. And then we can solve it by taking the Laplace transform of both sides they way we solve a integral equation of convolution type.

(Refer Slide Time: 32:37)

Example: Consider

$$y(x) = (\cos x - x - 2) + \int_a^x (t-x)y(t)dt.$$

Solution: Here $f(x) = \cos x - x - 2$, $\lambda=1$ and $K(x, t) = t - x$.
 Let $K(x, t) = b_0(t) + b_1(t) (t - x)$ then $b_0(t) = 0$, $b_1(t) = 1$.
 The resolvent kernel is given by

$$R(x, t; \lambda) = R(x, t; 1) = -\frac{d^2 h(x, t; 1)}{dt^2},$$

where $h(x, t; 1)$ satisfies the differential equation

$$\frac{d^2 h}{dt^2} + \lambda [b_0(t) + b_1(t)h] = 0$$

13

So with this I would like to conclude my lecture. Thank you very much for your attention.
