COURSE ON:  
APPLIED ELASTICITY

Lecture 36  
TORSION PROBLEMS I

Dr. Soham Roychowdhury  
School of Mechanical Sciences  
Indian Institute of Technology Bhubaneswar

The slide features a central portrait of Dr. Soham Roychowdhury. To his left, there are diagrams illustrating torsion: a beam under a downward load, a rectangular bar being twisted, and a 3D grid of a cube with axes labeled  $i, j, k$  and  $m, n, l$ . To his right, there are logos of IIT Bhubaneswar and a circular diagram showing shear stress distribution on a circular cross-section.

Welcome back to the course on Applied Elasticity. In today's lecture, we are going to start a new topic: torsion problems in elasticity.

**Simple Theory of Torsion**

Applicable for the circular shafts where the plane cross-sections remain plane without any distortion due to the application of twisting moment.

$$\frac{\tau}{r} = \frac{T}{J} = G\theta$$
$$\Rightarrow \theta = \frac{T}{GJ}$$

$r$ : Radius of circular cylinder  
 $T$ : Applied torque  
 $J$ : Polar moment of area  
 $G$ : Modulus of rigidity  
 $\theta$ : Angle of twist per unit length  
 $\tau$ : Maximum shear stress at the outer surface

Dr. Soham Roychowdhury Applied Elasticity

The slide includes a diagram of a circular shaft under torque  $T$ , showing the angle of twist  $\theta$  and the displacement  $\Delta$ . A small portrait of Dr. Soham Roychowdhury is in the bottom right corner.

First, we will briefly discuss the simple theory of torsion, which is valid for shafts with circular cross-sections. The simple theory of torsion, normally covered in undergraduate

solid mechanics courses, can only deal with prismatic bars or shafts with circular cross-sections. This theory assumes that plane cross-sections remain plane without any distortion during torsion.

If you consider a circular bar or a prismatic bar with a circular cross-section of radius  $r$ , which is free at one end and fixed at the other end, as shown in this figure. Let us apply a twisting moment or torque at the free end of this prismatic bar, where the magnitude of the torque is  $T$ . Due to the application of this torque, the bar will twist. Let us say  $\theta$  is the measure of the twist. So,  $\theta$  is the angle of twist per unit length of this circular bar.

This assumption states that plane cross-sections remain plane without any distortion. If you take any section here, you will get one circular cross-section before twisting. After twisting, the circular cross-section will remain a circle. Let us say this was before twisting; after twisting, these lines will simply shift, with no other difference observed. It will still be a circle, just rotated with respect to the centroidal axis. This is the meaning of that plane section remaining plane without any distortion, and as there is no distortion of the surface, the displacement component along this direction is equal to 0. So, displacement is equal to 0 along the axis of twist along the longitudinal axis of the bar. If these are true, then we can say the simple theory of torsion is applicable.

The simple theory of torsion can be used for solving torsion problems of the bar only with circular cross-sections. For any other cross-section, the distortion of the cross-section is unavoidable, and thus the simple theory of torsion cannot be used. For this particular theory, the relation between the applied torque, the resulting angle of twist per unit length  $\theta$ , and the generated shear stress  $\tau$  is like this:  $\frac{\tau}{r} = \frac{T}{J} = G\theta$ , where  $r$  is the radius of the circular cylinder,  $T$  is the applied torque,  $\theta$  is the angle of twist generated per unit length due to the torsion,  $G$  is the modulus of rigidity or shear modulus of the material,  $J$  is called the polar moment of area, and  $\tau$  is the maximum shear stress generated at the outer surface.

If this twist is applied on the circular cross-section, the maximum shear stress is expected at the outer surface. Let us say we are plotting the maximum shear stress. This will be the variation of  $\tau$ . So, at radius equal to  $r$  at the outer radius, we are going to have maximum

shear stress generated, and for the circular cross-section, which can be obtained by the simple theory of torsion, that  $\frac{\tau}{r} = \frac{T}{J} = G\theta$ , and from this, we can get a relation between  $\theta$  and  $T$  as  $\theta = \frac{T}{GJ}$ , where note that  $\theta$  is not the total angle of twist. This is the angle of twist per unit length. This particular theory is known to you. The limitation of this theory is that it is valid only for circular cross sections where distortion can be avoided.

**St. Venant's Theory of Torsion**

Valid for **non-circular** cross-sections too, with an assumption that the length of the prismatic bar is much larger than rest of the dimensions.  
 Along with the rotation of the cross-section, **warping** (displacement normal to the cross-section) is also considered.

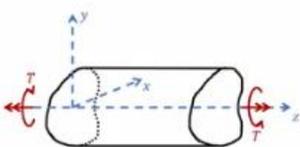

There are two different approaches under this theory:

**Warping Function Approach**  
 This approach starts with assumed displacement fields as

$$u = -\theta yz \quad v = \theta xz \quad w = \theta\psi(x, y)$$

$\theta$ : Angle of twist per unit length  
 $\psi(x, y)$ : Warping function

**Prandtl's Stress Function Approach**

Dr. Soham Roychowdhury Applied Elasticity

For any other cross section, there would be distortion, and thus this theory cannot be used. For that, we will be using Saint-Venant's theory of torsion. It is valid for non-circular cross sections, and allow out-of-plane displacement. This theory has one assumption: that the length of the prismatic bar is much larger compared to the other two dimensions. So, the cross-sectional dimensions are much smaller. They are much smaller compared to the length of the bar. Under that assumption, this particular Saint-Venant's theory of torsion is applicable, and it is valid for circular as well as non-circular cross sections, such as elliptic, triangular, rectangular cross-section bars, or any other arbitrary cross-sectional bars.

Let us consider a prismatic bar with  $z$  being the longitudinal axis, and it has some arbitrary cross section. You can clearly see this cross section is arbitrary, not varying along the length; the cross section is uniform, but the shape is not a simple circle - it has some arbitrary curve. This is subjected to a twisting moment  $T$  at both ends about the longitudinal axis  $z$ . This is the twisting of a prismatic bar with a general non-circular

cross section, which we will try to solve with the help of Saint-Venant's theory of torsion. Here, this theory allows out-of-plane displacement normal to the cross section.

For the simple theory of torsion, as I told, displacement along the  $z$ -axis is not allowed. Here, displacement along the  $z$ -axis, that is normal to the cross-section, is allowed. It is allowed to have a non-zero value, and this particular phenomenon is called the warping of the cross-section. So, for a circular cross-section, there would be no warping, resulting in zero out-of-plane displacement  $w$  along the  $z$ -direction. Whereas, for a non-circular shaft,  $w$  along the  $z$ -direction (out-of-plane displacement) will be non-zero, and hence we can say warping is occurring along with the twisting of the bar.

There are two different approaches for solving the problem of twist or torsion of non-circular bars. The first approach is called the warping function approach, whereas the second one is called the Prandtl stress function approach. For the warping function approach, it starts with the assumption of the displacement field, where the out-of-plane displacement  $w$  is chosen to be a function known as the warping function. The in-plane displacements  $u$  and  $v$  are chosen like this:  $u = -\theta yz$ ,  $v = \theta xz$ , and  $w = \theta\psi(x, y)$ .  $\psi(x, y)$  is called the warping function, which depends only on the cross-sectional variables  $x$  and  $y$ , and  $\theta$  is the same angle of twist per unit length.

Using this theory, starting with the displacement field, which includes this unknown warping function  $\psi$ , the torsion problem will be reduced to a problem of finding this warping function for the first approach, the warping function approach. Whereas, the second approach is based on the elasticity solution theory, where we will involve a stress function.

## Prandtl's Stress Function Approach

This is a semi-inverse approach.

Strain components:  $\varepsilon_{xx} = \varepsilon_{yy} = \varepsilon_{zz} = \varepsilon_{xy} = 0, \varepsilon_{yz} \neq 0, \varepsilon_{xz} \neq 0$

Stress components:  $\sigma_{xx} = \sigma_{yy} = \sigma_{zz} = \tau_{xy} = 0, \tau_{yz} \neq 0, \tau_{xz} \neq 0$

Equilibrium equations:

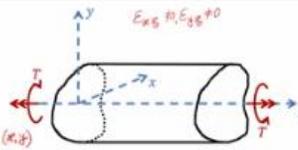

Neglecting body forces and assuming  $\tau_{xz}$  and  $\tau_{yz}$  being independent of  $z$ , the only equilibrium equation left to be satisfied is

$$\frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} = 0 \Rightarrow \frac{\partial^2 \phi}{\partial x \partial y} - \frac{\partial^2 \phi}{\partial y^2} = 0$$

which is automatically satisfied by the stress components defined in terms of a stress function  $\phi(x, y)$  as,

$$\tau_{xz} = \frac{\partial \phi(x, y)}{\partial y} \quad \tau_{yz} = -\frac{\partial \phi(x, y)}{\partial x}$$

where  $\phi(x, y)$  is known as the Prandtl's stress function.

In this lecture, we will talk about the Prandtl stress function approach for solving the Saint-Venant's theory of torsion, which is valid for non-circular cross-sections. In the Prandtl stress function approach, this uses a semi-inverse approach where the equilibrium equation, we will try to satisfy automatically by defining the stress components as partial derivatives of a stress function, which is known as the Prandtl stress function.

First, let us start with the strain components. For this particular type of torsion problem, when the twist is given about the  $z$ -axis and no axial forces are there along  $x$ ,  $y$ , and  $z$ , all the axial normal strains -  $\varepsilon_{xx}$ ,  $\varepsilon_{yy}$ ,  $\varepsilon_{zz}$  - should be 0. Applied torque about the  $z$ -axis can cause only two non-zero strains - non-zero shear strains:  $\varepsilon_{yz}$  and  $\varepsilon_{xz}$ . These two are only not equal to 0 as  $T$  is applied about  $z$ -axis and another in-plane shear strain  $\varepsilon_{xy}$  should also be 0.

With this, we have 4 stress components to be 0, and only 2 out-of-plane shear strains  $\varepsilon_{xz}$  and  $\varepsilon_{yz}$  are non-zero. As no axial forces (no normal forces) are there, all the normal strains are 0 and in-plane normal shear strain  $\varepsilon_{xy}$  is also 0, and only 2 out-of-plane shear strains will be resulted due to application of the torque about  $z$ -axis. With the help of these strain components, we can obtain the stress components.

Now, all three normal strains being 0, we must have all three normal stresses to be 0. As  $\varepsilon_{xy}$  is 0, the corresponding shear stress  $\tau_{xy}$  would also be 0. However, these two -  $\tau_{yz}$  and  $\tau_{xz}$ , the out of plane shear stresses - would be non-zero as the corresponding strain components are non-zero.

Coming to the equilibrium equation, as four of the stress components are 0 and we are going to neglect the body forces, with that, out of three equilibrium equations, we will be left with only one equilibrium equation.  $\sigma_{xx}$ ,  $\sigma_{yy}$ ,  $\sigma_{zz}$ ,  $\tau_{xy}$  are set to 0, body forces are neglected, and we are also assuming that  $\tau_{xz}$  is function of  $x$  and  $y$  only, and similarly,  $\tau_{yz}$  is also function of  $x$  and  $y$  only.

These are independent of  $z$  because the cross section is uniform; along  $z$ , the cross section is not changing. The applied torque is not changing, that is also constant along  $z$ . So, this resultant shear stresses  $\tau_{xz}$  and  $\tau_{yz}$  must be independent of  $z$ ; they are non-zero but not dependent on  $z$ . So, the  $\frac{\partial \tau_{xz}}{\partial z}$  term is 0, and the  $\frac{\partial \tau_{yz}}{\partial z}$  term is also 0. Putting all these assumptions into the equilibrium equation, the two equilibrium equations would be automatically satisfied along the  $x$  and  $y$  axes.

The  $z$ -axis equilibrium equation would be the only remaining one, as  $\frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} = 0$ . This equation can be automatically satisfied if we define these two non-zero stress components,  $\tau_{xz}$  and  $\tau_{yz}$ , in terms of a stress function of this particular form:  $\tau_{xz} = \frac{\partial \phi}{\partial y}$ , and  $\tau_{yz} = -\frac{\partial \phi}{\partial x}$ . So, if you substitute  $\tau_{xz}$  as  $\frac{\partial \phi}{\partial y}$ , the first term will be  $\frac{\partial^2 \phi}{\partial x \partial y}$ , and the second term, substituting  $\tau_{yz}$  as  $-\frac{\partial \phi}{\partial x}$ , would be  $-\frac{\partial^2 \phi}{\partial y \partial x}$ . These two would cancel each other, and thus, this equation is automatically satisfied.

So, this particular choice of stress function,  $\phi$ , is called the Prandtl stress function, which is used for solving torsion problems of non-circular bars. We have reduced our problem to a single unknown problem where  $\phi(x, y)$ , the Prandtl stress function, is the only unknown we need to solve. And with respect to that, using these two equations, the shear stress components are obtained, which all automatically satisfy the equation of equilibrium.

## Prandtl's Stress Function Approach

Strain fields:

$$\epsilon_{xx} = \epsilon_{yy} = \epsilon_{zz} = \epsilon_{xy} = 0$$

$$\epsilon_{xz} = \frac{\tau_{xz}}{2G} = \frac{1}{2G} \frac{\partial \phi(x,y)}{\partial y} \quad \text{and} \quad \epsilon_{yz} = \frac{\tau_{yz}}{2G} = -\frac{1}{2G} \frac{\partial \phi(x,y)}{\partial x}$$

$$\tau_{xz} = \frac{\partial \phi(x,y)}{\partial y} \quad \tau_{yz} = -\frac{\partial \phi(x,y)}{\partial x}$$

$$\frac{\partial}{\partial z} (\epsilon_{xz}) = 0$$

[as  $\epsilon_{xz}$  and  $\epsilon_{yz}$  are independent of  $z$ ]

$$\frac{\partial}{\partial z} (\epsilon_{yz}) = 0$$

Strain compatibility equations:

$$\frac{\partial^2 \epsilon_{xx}^0}{\partial y^2} + \frac{\partial^2 \epsilon_{yy}^0}{\partial x^2} - 2 \frac{\partial^2 \epsilon_{xy}^0}{\partial x \partial y} = 0$$

$$\frac{\partial}{\partial z} \left( \frac{\partial \epsilon_{xz}}{\partial x} + \frac{\partial \epsilon_{yz}}{\partial y} - \frac{\partial \epsilon_{xy}}{\partial z} \right) = \frac{\partial^2 \epsilon_{xz}}{\partial x \partial y} = \frac{\partial^2 \epsilon_{yz}}{\partial x \partial z} + \frac{\partial^2 \epsilon_{xy}}{\partial y \partial z} = 0$$

$$\frac{\partial}{\partial x} \left( -\frac{\partial \epsilon_{yz}}{\partial x} + \frac{\partial \epsilon_{xz}}{\partial y} + \frac{\partial \epsilon_{xy}}{\partial z} \right) = \frac{\partial^2 \epsilon_{yz}}{\partial y \partial z} = -\frac{\partial^2 \epsilon_{xz}}{\partial x^2} + \frac{\partial^2 \epsilon_{xy}}{\partial x \partial y} = 0$$

$$\frac{\partial}{\partial y} \left( \frac{\partial \epsilon_{yz}}{\partial x} - \frac{\partial \epsilon_{xz}}{\partial y} + \frac{\partial \epsilon_{xy}}{\partial z} \right) = \frac{\partial^2 \epsilon_{yz}}{\partial x \partial z} = \frac{\partial^2 \epsilon_{xz}}{\partial x \partial y} - \frac{\partial^2 \epsilon_{xy}}{\partial y^2} = 0$$

Automatically satisfied

Dr. Soham Roychowdhury Applied Elasticity

Moving forward, we will try to derive the strain fields. So, these two  $\tau_{xz}$  and  $\tau_{yz}$  are defined in terms of  $\phi$  as  $\frac{\partial \phi}{\partial y}$  and  $-\frac{\partial \phi}{\partial x}$ , respectively. The two corresponding non-zero strain components,  $\epsilon_{xz}$  and  $\epsilon_{yz}$ , can be written as follows:  $\epsilon_{xz} = \frac{1}{2G} \frac{\partial \phi}{\partial y}$ ,  $\epsilon_{yz} = -\frac{1}{2G} \frac{\partial \phi}{\partial x}$ , and the rest of the strain components ( $\epsilon_{xx}$ ,  $\epsilon_{yy}$ ,  $\epsilon_{zz}$ , and  $\epsilon_{xy}$ ) are all 0, as we had already discussed. These are the two non-zero strain components we are left with.

Now, these two non-zero strains must satisfy the strain compatibility equation to ensure a unique displacement field. Since four of the strain components are already zero, many of the strain-displacement equations would be automatically satisfied. First, let us write down all six strain-displacement compatibility equations. Here, you can see the six strain-displacement compatibility equations are written. The first 3 are of similar nature, whereas these 3 are of similar nature.

Now, on these 6 equations, we will impose these 4 strain constant components to be 0:  $\epsilon_{xx}$ ,  $\epsilon_{yy}$ ,  $\epsilon_{zz}$ ,  $\epsilon_{xy}$  to be 0. If we enforce that, these many terms will go to 0. After that, the last 3 equations will only be left with 3 terms: 2 terms on the left-hand side, and the right-hand side we are having a 0 term. Here, once again, we will check this expression of the non-zero strain components:  $\epsilon_{xz}$ ,  $\epsilon_{yz}$ . These 2 are dependent on  $\phi$  only, where  $\phi$  is a function of  $x$  and  $y$ .

So,  $\phi$  is independent of  $z$ , meaning  $\epsilon_{xz}$  and  $\epsilon_{yz}$  are also independent of  $z$ . Thus, this term:

$\frac{\partial^2 \epsilon_{xz}}{\partial x \partial z}$  will also go to 0. Whenever you are having  $\frac{\partial}{\partial z}$  term of this  $\epsilon_{xz}$ , that would be 0.

Similarly,  $\frac{\partial \varepsilon_{yz}}{\partial z}$  would also go to 0. Setting all those to 0 because  $\phi$  is independent of  $z$ , we will see the first 4 equations. These four strain compatibility equations are automatically satisfied. We are only left with these two strain compatibility equations, which our displacement and strain fields should satisfy to ensure unique displacement components.

**Prandtl's Stress Function Approach**

$$-\frac{\partial^2 \varepsilon_{yz}}{\partial x^2} + \frac{\partial^2 \varepsilon_{xz}}{\partial x \partial y} = 0 \Rightarrow \frac{\partial}{\partial x} \left( \frac{\partial \varepsilon_{xz}}{\partial y} - \frac{\partial \varepsilon_{yz}}{\partial x} \right) = 0$$

$$\frac{\partial^2 \varepsilon_{yz}}{\partial x \partial y} - \frac{\partial^2 \varepsilon_{xz}}{\partial y^2} = 0 \Rightarrow -\frac{\partial}{\partial y} \left( \frac{\partial \varepsilon_{xz}}{\partial y} - \frac{\partial \varepsilon_{yz}}{\partial x} \right) = 0$$

$$\left\{ \begin{array}{l} \varepsilon_{xz} = \frac{1}{2G} \frac{\partial \phi(x,y)}{\partial y} \\ \varepsilon_{yz} = -\frac{1}{2G} \frac{\partial \phi(x,y)}{\partial x} \end{array} \right.$$

As  $\left( \frac{\partial \varepsilon_{xz}}{\partial y} - \frac{\partial \varepsilon_{yz}}{\partial x} \right)$  is function of  $x$  and  $y$  only and its partial derivatives with respect to both  $x$  and  $y$  vanish,

$$\frac{\partial \varepsilon_{xz}}{\partial y} - \frac{\partial \varepsilon_{yz}}{\partial x} = \text{Constant} = -\theta \quad (\text{assumed to match the results with another approach})$$

$$\Rightarrow \frac{1}{2G} \frac{\partial^2 \phi}{\partial y^2} + \frac{1}{2G} \frac{\partial^2 \phi}{\partial x^2} = -\theta$$

$$\Rightarrow \nabla^2 \phi = -2G\theta$$

This condition must be satisfied by the Prandtl's stress function  $\phi(x, y)$  over the total domain.

Moving forward, starting with these two, these two can be rewritten in this form. The first equation would be  $\frac{\partial}{\partial x} \left( \frac{\partial \varepsilon_{xz}}{\partial y} - \frac{\partial \varepsilon_{yz}}{\partial x} \right) = 0$ , and the second term is  $-\frac{\partial}{\partial y} \left( \frac{\partial \varepsilon_{xz}}{\partial y} - \frac{\partial \varepsilon_{yz}}{\partial x} \right) = 0$ .

You can see the term remaining within the bracket is the same for both equations. So,  $\frac{\partial}{\partial x}$ , the partial derivative with respect to  $x$  of that term, is 0, and the partial derivative with respect to  $y$  of that term is 0, and this term is only a function of  $x$  and  $y$ . This can be true only if this entire term within the bracket is a constant. So, if the partial derivative of this function,  $\frac{\partial \varepsilon_{xz}}{\partial y} - \frac{\partial \varepsilon_{yz}}{\partial x}$ , is vanishing for both partial derivatives with respect to  $x$  and with respect to  $y$ , that means this term must be a constant.

Let us choose that constant to be  $-\theta$ . Why minus  $\theta$ ? This is our choice; we can assign any name to this constant. If I choose this as  $-\theta$ , we will be able to match the obtained equation with the equations derived from another approach, the warping function approach. You can take any other name, like  $c$  or something, but if you do, you will eventually have to relate this solution to the warping function solution, and then we will derive a relation with  $\theta$ , the angle of twist per unit length. So, to match the results of the

two different approaches, we are choosing this constant to be  $-\theta$ , and the angle of twist is obviously a constant since the applied torque is constant.

Substituting  $\varepsilon_{xz}$  and  $\varepsilon_{yz}$  in terms of  $\phi$ . We know  $\varepsilon_{xz}$  and  $\varepsilon_{yz}$  in terms of  $\phi$ . If you substitute it back here, this equation would be  $\frac{1}{2G} \left( \frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} \right) = -\theta$ . So,  $\frac{1}{2G} \nabla^2 \phi = -\theta$ . And  $\nabla^2 \phi$  can be written as  $-2G\theta$ . This is the governing equation we need to solve or use to choose  $\phi$ .

$\phi$  must satisfy this equation:  $\nabla^2 \phi = -2G\theta$ , and this should be satisfied over the entire domain. Over the total problem domain, over the entire cross-section, the Prandtl stress function  $\phi$  must satisfy this particular equation. If you recall for the bending problem, the governing equation was the bi-harmonic equation. The choice of  $\phi$  must satisfy the bi-harmonic condition. Here, that is not so.

The chosen stress function, the Prandtl stress function, must satisfy this equation:  $\nabla^2 \phi = -2G\theta$ . Only then can this be used as a possible stress function for the torsion problem because only then the strain compatibility equation would be satisfied, and this should be satisfied over the entire domain for all values of  $x$  and  $y$ . After this, let us see if we are supposed to impose any more conditions on the choice of  $\phi$ .

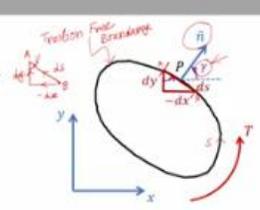

**Prandtl's Stress Function Approach**

**Boundary conditions:**  
 For this torsion problem, the boundary of the bar is free of any surface traction/stress.

From geometry,  $\frac{dx}{ds} = -\sin \gamma$  and  $\frac{dy}{ds} = \cos \gamma$

At point  $P$ , the direction cosines of  $\bar{n}$  are calculated as,

$\Rightarrow n_x = \cos \gamma$   
 $n_y = \cos \left( \frac{\pi}{2} - \gamma \right) = \sin \gamma$   
 $n_z = \cos \left( \frac{\pi}{2} \right)$

$ds$ : Elemental length along the boundary  
 $\bar{n}$ : Unit normal vector on boundary at point  $P$

Dr. Soham Roychowdhury Applied Elasticity

That should be imposed on the basis of the boundary conditions of the problem. For the torsion problem, as the the lateral surface of the prismatic bar is free of any kind of

surface fractions or stresses, that boundary should be free of stress. This condition is required to be imposed.

Let us consider this particular boundary. We are looking from the  $z$ -axis, so, the boundary curve is given. This is a traction free boundary. We are not having any surface traction present along this boundary. As this is a traction free boundary, we should have all the surface traction components  $t_x, t_y, t_z$  should be 0. Now, we are choosing a point  $P$  on the boundary, and along that,  $ds$  is a small elemental length;  $s$  being a path coordinate here. Along the boundary, the coordinate is taken to be  $s$ .

So, we are taking a small length of  $ds$  from here to here around point  $P$  and  $\hat{n}$  is the unit normal at point  $P$  on the boundary curve  $\Gamma$ . This  $ds$ , as you are going along the boundary, along  $s$  direction, this instead of going along the boundary we can say we are going like this. First we are going along the negative  $x$ -axis by amount  $-dx$ , then, we are going on the along the positive  $y$ -axis by amount  $dy$ .

Let us say this is a point  $A$ , this is a point  $B$ , and we are starting from point  $B$  going to point  $A$ . One possible option is going along the boundary  $ds$  which is basically arc, not a straight line, but if  $ds$  is very small, we can assume this arc to be almost a straight line. Another alternate path instead of going from  $B$  to  $A$  along  $ds$ , we can go along  $-dx$ , along the negative  $x$ -axis and then along the  $y$ -axis, we can go by an amount  $dy$ . With that also, we can reach point  $A$ . So, the  $d\tilde{s}$  vector is nothing but  $-dx\hat{i} + dy\hat{j}$ .

Like that, we can also write the  $d\tilde{x}$  vector. Now, from geometry, considering this angle being  $\gamma$ ,  $\gamma$  is the angle that the unit normal  $\hat{n}$  is making with the  $x$ -axis. From this triangle, this angle is  $\gamma$ . From there, we can write  $\frac{dx}{ds}$  as  $-\sin \gamma$  and  $\frac{dy}{ds}$  as  $\cos \gamma$ . The base of the triangle is  $-dx$ , the height is  $dy$ , and with that,  $\sin \gamma$  is  $-\frac{dx}{ds}$ , and  $\cos \gamma$  is  $\frac{dy}{ds}$ .

Now, if you are writing the direction cosines for this unit normal  $\hat{n}$ , the cosine of the angle this unit normal is making along the  $x$ ,  $y$ , and  $z$  axes at point  $P$ , If we write those, we are naming them as  $n_x, n_y$ , and  $n_z$ . These are the direction cosines of the unit normal

$\hat{n}$  at boundary point  $P$ .  $n_x$  is the cosine of the angle that the  $\hat{n}$  vector is making with the  $x$ -axis, which is nothing but  $\gamma$ .

So,  $n_x$  is  $\cos \gamma$ .  $n_y$  is the cosine of the angle that the  $\hat{n}$  vector is making with the  $y$ -axis, which is  $90^\circ - \gamma$ . So,  $\cos(90^\circ - \gamma)$ , which is nothing but  $\sin \gamma$ , and  $n_z$  is the angle the  $\hat{n}$  vector is making with the  $z$ -axis. The  $z$ -axis is perpendicular to the  $xy$ -plane on which the  $\hat{n}$  vector is lying. So, this  $n_z$  should be  $\cos(90^\circ)$ , the  $z$ -axis being orthogonal to the plane containing  $\hat{n}$ , and thus, this would be 0. Substituting  $\sin \gamma$  as  $-\frac{dx}{ds}$  and  $\cos \gamma$  as  $\frac{dy}{ds}$ , we can write  $n_x$  as  $\frac{dy}{ds}$ ,  $n_y$  as  $-\frac{dx}{ds}$ , and  $n_z$  as 0.

**Prandtl's Stress Function Approach**

As the boundary is traction free, all resultant traction components at point  $P$  must vanish as

$$t_x^n = \sigma_{xx}n_x + \tau_{xy}n_y + \tau_{xz}n_z = 0$$

$$t_y^n = \tau_{yx}n_x + \sigma_{yy}n_y + \tau_{yz}n_z = 0$$

$$t_z^n = \tau_{zx}n_x + \tau_{zy}n_y + \sigma_{zz}n_z = 0$$

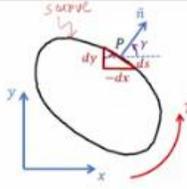

Automatically satisfied  $[\sigma_{xx} = \sigma_{yy} = \sigma_{zz} = \tau_{xy} = 0]$

$$\Rightarrow \tau_{xz} \frac{dy}{ds} + \tau_{yz} \left(-\frac{dx}{ds}\right) = 0 \Rightarrow \frac{\partial \phi}{\partial y} \frac{dy}{ds} + \left(-\frac{\partial \phi}{\partial x}\right) \left(-\frac{dx}{ds}\right) = 0$$

$$\Rightarrow \frac{\partial \phi}{\partial x} \frac{dx}{ds} + \frac{\partial \phi}{\partial y} \frac{dy}{ds} = 0 \Rightarrow \frac{\partial \phi}{\partial s} = 0$$

This shows that the stress function  $\phi(x, y)$  must be constant along the boundary.

In case of singly connected boundary, this constant is chosen as zero, i.e., along the boundary,  $\phi = 0$

$$\tau_{xz} = \frac{\partial \phi(x, y)}{\partial y}$$

$$\tau_{yz} = -\frac{\partial \phi(x, y)}{\partial x}$$

Dr. Soham Roychowdhury Applied Elasticity

Moving forward, as this entire boundary is free of any kind of traction, all the surface traction components  $t_x^n$ ,  $t_y^n$ , and  $t_z^n$  must be 0 over the boundary. For the entire boundary, we must have all three equations to be satisfied:  $t_x^n = 0$ ,  $t_y^n = 0$ ,  $t_z^n = 0$ . Using the relation between the Cauchy stress components and surface traction components, like  $\tilde{t} = \tilde{\sigma} \tilde{n}$  or  $\tilde{\sigma}^T \tilde{n}$ . And  $\tilde{\sigma}$  and  $\tilde{\sigma}^T$  are the same due to the symmetry of  $\tilde{\sigma}$ .

Expanding this into the  $x$ ,  $y$ , and  $z$  directions, we will be getting these three equations. We already know that  $\sigma_{xx}$ ,  $\sigma_{yy}$ ,  $\sigma_{zz}$  and  $\tau_{xy}$  are 0 for the torsion problems. Those terms will go to 0 and also  $n_x$ ,  $n_y$ ,  $n_z$  we had evaluated out of which  $n_z$  is 0,  $n_x$  is  $\frac{dy}{ds}$ ,  $n_y$  is  $-\frac{dx}{ds}$ . Setting  $n_z$  to be 0, the first two equations would be automatically satisfied, and we will be left with only one equation which is the last equation  $\tau_{xz} \frac{dy}{ds} + \tau_{yz} \left(-\frac{dx}{ds}\right) = 0$ .

Here, we are substituting  $\tau_{xz}$  and  $\tau_{yz}$  in terms of stress function  $\phi$ , and if you simplify this, cancel the minus sign, this equation would be coming out as  $\frac{\partial \phi}{\partial x} \frac{dx}{ds} + \frac{\partial \phi}{\partial y} \frac{dy}{ds} = 0$ .

Now,  $\phi$  is function of  $x$  and  $y$ , and  $ds$  can be written in terms of  $dx$  and  $dy$ . Thus, this equation is nothing but  $\frac{\partial \phi}{\partial s} = 0$ , or we can even write  $\frac{d\phi}{ds} = 0$ . So, along the path coordinate  $s$ ,  $\phi$  cannot change if  $\frac{\partial \phi}{\partial s} = 0$  means  $\phi$  should be constant along  $s$ . This boundary curve is defined by this  $s$  curve. Along the  $s$  curve,  $\phi$  must be constant. This means the Prandtl stress function,  $\phi$ , must be constant along the boundary. This is another constraint we are having.  $\nabla^2 \phi = -2G\theta$  over entire domain for all values of  $x$  and  $y$ , and  $\phi$  must be constant along the boundary.

For the case of singly connected boundary, like this, means we are not having any hollow pipe, only outer boundary is existing, for such cases we choose that constant to be 0. The condition  $\phi = 0$  should be satisfied along the boundary. The Prandtl stress function must satisfy these two conditions:  $\phi = 0$  along the boundary, and  $\nabla^2 \phi = -2G\theta$ .

**Prandtl's Stress Function Approach**

Torque acting on the prismatic bar:

$$T = \iint (x\tau_{yz} - y\tau_{xz}) dx dy = - \iint \left( x \frac{\partial \phi}{\partial x} + y \frac{\partial \phi}{\partial y} \right) dx dy$$

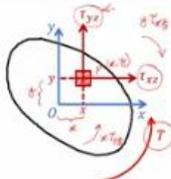

$$= - \iint \left[ \frac{\partial}{\partial x} (x\phi) + \frac{\partial}{\partial y} (y\phi) \right] dx dy + 2 \iint \phi dx dy$$

Using the Green's theorem for the first two terms,  $\iint \left( \frac{\partial M}{\partial x} - \frac{\partial L}{\partial y} \right) dx dy = \oint (L dx + M dy)$

$$T = - \oint (x\phi dy - y\phi dx) + 2 \iint \phi dx dy$$

Boundary integral      Area integral

As  $\phi = 0$  along the boundary, the boundary integral vanishes, and thus

$$T = 2 \iint \phi(x, y) dx dy$$

Dr. Soham Roychowdhury Applied Elasticity

Coming to the relation between the torque and the angle of twist. Let us try to derive the expression for torque. The torque acting on the system with a non-circular cross-section can be written in terms of the generated stress components as follows:  $T = \iint (x\tau_{yz} - y\tau_{xz}) dx dy$ . Let us consider this particular cross-section figure, where I am taking an element at point  $P$ , which is subjected to  $\tau_{xz}$  acting on the  $z$ -plane, along the  $x$ -axis, and

$\tau_{yz}$  acting upward at point  $P$  on the  $z$ -plane, along the  $y$ -axis. Now, both of them will create some torque about point  $O$ .

If you first consider  $\tau_{yz}$ , This point  $P$  has coordinates  $(x, y)$ . This distance is  $x$ , and this distance is  $y$ , thus, the torque created by  $\tau_{yz}$  is  $x\tau_{yz}$  created in the counterclockwise direction due to this component. Similarly,  $\tau_{xz}$  creates a clockwise torque of  $y\tau_{xz}$  about point  $O$ . Since it is clockwise - opposite to the previous torque due to  $\tau_{yz}$  - we add a minus sign. So, this first term is the torque due to  $\tau_{yz}$ . The second term is the torque due to  $\tau_{xz}$ . They are opposite in nature. We are taking counterclockwise torque to be positive.

This is net torque due to stress distribution for the small element around point  $P$  of  $dx$ ,  $dy$  side lengths. So, total torque over the entire domain entire cross section will be  $\iint (x\tau_{yz} - y\tau_{xz}) dx dy$  and that should be or must be equal to this applied torque  $T$  from the balance of the torque because this torque results this particular stresses the non-zero shear stresses -  $\tau_{xz}$  and  $\tau_{yz}$ . Substituting  $\tau_{xz}$ ,  $\tau_{yz}$  in terms of  $\phi$ , this equation will be like this.

We can further simplify this in this particular fashion where  $x \frac{\partial \phi}{\partial x} + y \frac{\partial \phi}{\partial y}$  is written as two sets of integral:  $2\phi$  we are adding, and  $2\phi$  we are subtracting. So that the first term becomes  $\iint \left( -\frac{\partial}{\partial x}(x\phi) + \frac{\partial}{\partial y}(y\phi) \right) dx dy + \iint 2\phi dx dy$ . If you expand these two partial derivatives using the chain rule, then one term will get cancelled and we will be getting this initial one back. Using the Green's theorem, the first area integral is converted into the boundary integral as:  $\iint \left( \frac{\partial M}{\partial x} - \frac{\partial L}{\partial y} \right) dx dy = \oint (L dx + M dy)$ . This first area integral term is converted into a boundary integral term of  $-\oint (x\phi dy - y\phi dx) + 2 \iint \phi dx dy$ .

If you recall, over the entire boundary, this term  $\phi$  must be 0. This is equal to 0 along the boundary and hence, this boundary integral term would vanish and total  $T$  will just be  $2 \iint \phi dx dy$ . Applied torque is twice integral of the Prandtl stress function. As the boundary integral term vanish, we will only be left out with area integral term.

## Summary

- Simple Theory of Torsion
- St. Venant's Theory of Torsion
- Prandtl's Stress Function Approach

In this lecture, we discussed the simple theory of torsion and then, introduced the Saint-Venant's theory of torsion, which is valid for both circular and non-circular cross-section. And then, in detail, we discussed the solution technique for the Prandtl stress function approach to torsion problems.

Thank you.
